been given via continuous IV infusion.[42,45] Desirudin has a terminal elimination half-life after subcutaneous dosing of approximately 2 hours, and 80% to 90% of the elimination is by renal clearance and metabolism. The total urinary excretion of unchanged drug amounts to 40% to 50% of the administered dose. Similar to lepirudin, in patients with moderate to severe renal impairment, the dosage should be reduced (see Table 26–12). Although antihirudin antibodies also have been documented with desirudin, the incidence appears to be lower than with lepirudin.[42,46]

Bivalirudin, formerly known as Hirulog, is a semisynthetic 20-amino-acid polypeptide analogue of recombinant hirudin that is FDA approved for use in patients with unstable angina who are undergoing percutaneous transluminal coronary angioplasty and with provisional use of glycoprotein IIb/IIIa inhibitor for use as an anticoagulant in patients undergoing percutaneous coronary intervention.[47] Recent reports also support the use of bivalirudin in patients with acute ST elevation myocardial infarction and in patients with HIT, although the agent is not currently FDA approved for these indications. Unlike lepirudin, bivalirudin is a reversible inhibitor of thrombin and provides transient antithrombotic activity with an estimated 20 to 30 minute half-life. This difference may reduce the risk of bleeding and antibody production.[42,48] The ACT can be used to monitor the anticoagulant effect of bivalirudin. Therapeutic ACT levels are achieved within 5 minutes after initiating bivalirudin therapy, and ACT levels return to subtherapeutic levels within 1 hour of discontinuing the infusion. The aPTT test has also been used to monitor the anticoagulant effect of bivalirudin in patients with HIT. Bivalirudin is mostly cleared by proteolytic cleavage and by hepatic metabolism, with approximately 20% eliminated renally. The manufacturer recommends reducing the dose by 20% to 60% in patients with renal impairment and monitoring the ACT closely (see Table 26–12).[42,48]

Argatroban differs from the hirudins in that it is a small, synthetic molecule derived from arginine that reversibly binds only to

the active catalytic site of thrombin. Its small size relative to other DTIs enables it to inhibit both clot-bound and soluble thrombin, offering a potential therapeutic advantage over other agents in its class.[42,49] Argatroban is primarily eliminated by hydroxylation and aromatization in the liver to inactive metabolites. A small percentage is excreted unchanged in the bile. The elimination half-life is 39 to 51 minutes, but extends to approximately 181 minutes in hepatic impairment. Dose adjustment is required in patients with hepatic impairment (see Table 26–12). The aPTT and ACT can be used to monitor the anticoagulant effect of argatroban. It is FDA approved for the prophylaxis or treatment of thrombosis in patients with HIT, and also as an anticoagulant in patients with HIT, or at risk of HIT, who are undergoing percutaneous coronary intervention.[42,50]

Oral Direct Thrombin Inhibitors

Recent progress has also been made in the development of oral DTIs. These agents appear promising and offer various advantages such as oral administration, predictable pharmacokinetics and pharmacodynamics, a broader therapeutic window, no need for routine laboratory monitoring, no significant drug interactions, and fixed dose administration without the need of dosing adjustments.[42] Several of these compounds are being investigated with dabigatran etexilate being in most advanced phases of clinical development. A previous oral DTI (ximelagatran) was denied FDA approval because of concerns of drug-induced liver toxicity. Dabigatran is being investigated in the prevention and treatment of venous thrombosis and for stroke prevention in atrial fibrillation. Available data suggest that dabigatran is at least as effective and safe as LMWH in the prevention of VTE after major orthopedic surgery and at least as effective and safe as warfarin in patients with atrial fibrillation.[51,52] Dabigatran has been approved in Canada and Europe for VTE prevention after hip and knee replacement surgery, but it is not yet approved by the FDA. Dabigatran shows promise as an effective and convenient oral anticoagulant. The first safe, oral DTI to make it to the U.S. market has the potential to revolutionize the provision of antithrombotic therapy.

Therapeutic Monitoring

Although the DTIs produce changes in the prothrombin time, the aPTT is used to monitor the patient's response to lepirudin, desirudin, and argatroban.[42,45] After obtaining baseline coagulation studies, doses of lepirudin and argatroban should be titrated to achieve the institution-specific therapeutic range or an aPTT 1.5 to 3.0 times the mean normal control. Daily aPTT monitoring is also recommended for patients on desirudin, particularly those with impaired renal function.[46] Although bivalirudin doses should be adjusted based on the ACT, some experience is also available using the aPTT.[47,48] The ecarin clotting time is a potentially more suitable test to measure the antithrombotic activity of the DTIs, but it is not readily available in most clinical labs in the United States. Oral DTIs appear to produce a predictable antithrombotic response in fixed doses and have a relatively large therapeutic window.[42] Consequently, routine anticoagulation monitoring may not be required for these agents. A CBC should be obtained at baseline and periodically thereafter to detect potential bleeding.

Adverse Effects

Contraindications for use of the DTIs and risk factors for bleeding are similar to other antithrombotic drugs (see Tables 26–8, 26–9). Hemorrhage is the most serious and common adverse effect related to the DTIs.[42,45] In studies evaluating the use of lepirudin for the treatment of patients with HIT, the incidence of major bleeding was relatively high (13%–17%).[43] However, no fatal or intracranial bleeding events occurred. A slightly lower rate of major hemorrhage was reported in HIT trials using argatroban (approximately 5%) and, similarly, there were no reports of fatal or intracranial bleeding.[50] Bleeding complications with desirudin were similar to enoxaparin in a trial of patients undergoing elective hip surgery. Serious bleeding occurred in less than 1% of all patients in the trial.[46] Minor bleeding and small reductions in red blood cell counts occurred relatively frequently but typically did not require drug discontinuation. There are no known agents that reverse the activity of the DTIs. Nonhemorrhagic effects such as fever, nausea, vomiting, and allergic reactions occur infrequently.

Drug–Drug and Drug–Food Interactions

The concurrent use of DTIs and thrombolytic agents substantially increases bleeding risk, particularly intracranial hemorrhage, and should be undertaken with great caution. Warfarin and antiplatelet agents can be concurrently initiated with DTIs. Because the DTIs prolong the PT and INR, close monitoring for bleeding complications is required. Few pharmacokinetic drug interactions with this class of agents are known. Drugs that alter renal function could prolong lepirudin, desirudin, and bivalirudin activity. Drugs that inhibit liver enzymes have the potential to interact with argatroban.[43,47,50,53]

Use in Special Populations

Lepirudin, bivalirudin, and argatroban are classified by the FDA as pregnancy category B drugs but they should be used cautiously in women of child bearing age because experience is very limited.[43,47,50] Desirudin is classified as pregnancy category C with no controlled trials in pregnant women. Lepirudin and argatroban have been evaluated in a very small number of children. Dosing requirements can vary widely in pediatric patients, thus product-specific dosing guidelines and monitoring should be followed.[54] Critically ill patients and patients with renal or hepatic impairment will require dosage adjustments according to the specific DTI used, and lower initiation doses are recommended (see Table 26–12).[55]

WARFARIN

The most widely prescribed anticoagulant worldwide is warfarin sodium.[4] It was serendipitously discovered in the early 1940s at the University of Wisconsin after hemorrhagic deaths occurred in cattle eating spoiled sweet clover. Warfarin is currently the anticoagulant of choice when long-term or extended anticoagulation is indicated. Warfarin is FDA approved for the prevention and treatment of VTE, as well as for the prevention of thromboembolic complications associated with atrial fibrillation, heart valve replacement, and myocardial infarction.[56] Because of its narrow therapeutic index, predisposition to drug and food interactions, and propensity to cause hemorrhage, warfarin requires continuous patient monitoring and education to achieve optimal outcomes.[4]

Pharmacology

Warfarin exerts its anticoagulation effect by inhibiting the enzymes responsible for the cyclic interconversion of vitamin K in the liver (Fig. 26–7).[4] Reduced vitamin K is a cofactor required for the carboxylation of the vitamin K-dependent coagulation proteins, namely factors II (prothrombin), VII, IX, and X, as well as the endogenous anticoagulant proteins C and S. Carboxylation of the N-terminal region of these proteins in the liver is required for biologic activity. By inhibiting the supply of vitamin K to serve as a cofactor in the production of these proteins, warfarin results in the production of partially carboxylated and decarboxylated coagulation proteins with reduced activity.[4] Warfarin has no direct effect on previously circulating clotting factors or previously formed thrombus. The time required for warfarin to achieve its pharmacologic

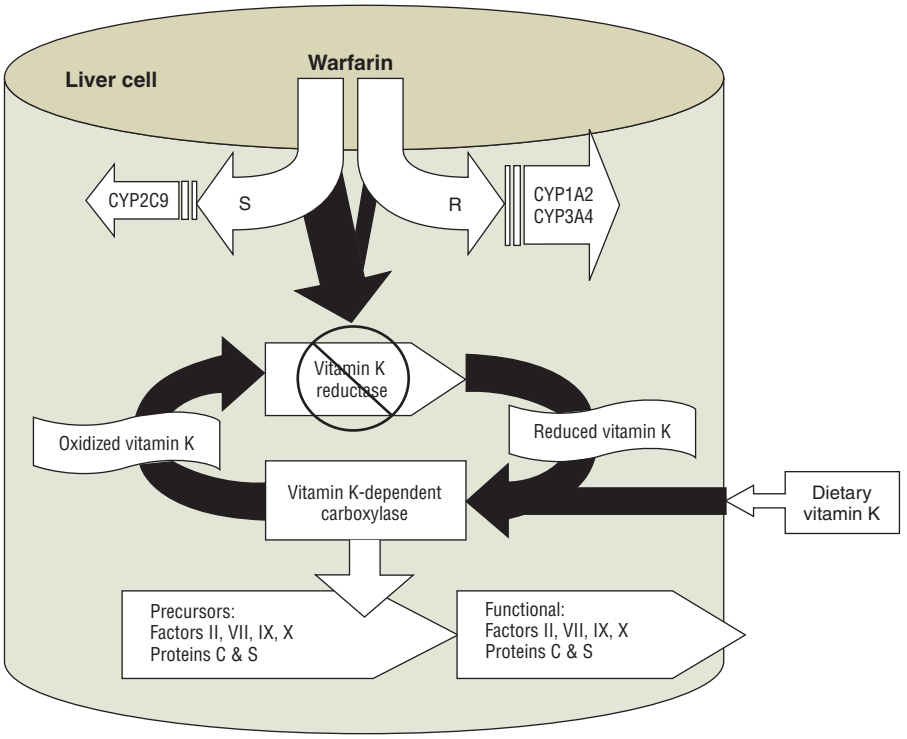

FIGURE 26-7. Pharmacologic activity and metabolism of warfarin.

effect is dependant on the elimination half-lives of the coagulation proteins (Table 26–13). Given that prothrombin has a 2- to 3-day half-life, warfarin's full antithrombotic effect is not achieved for 8 to 15 days after the initiation of therapy. By suppressing the production of clotting factors, warfarin prevents the initial formation and propagation of thrombus.[4]

Pharmacokinetics

Commercially available warfarin is a racemic mixture of *R* and *S* isomers. The *S* isomer is 2.7 to 3.8 times more potent that the *R* isomer.[4] Warfarin is rapidly and extensively absorbed from the gastrointestinal tract and reaches peak plasma concentration within 4 hours with a bioavailability of greater than 90% following oral administration. Warfarin is 99% bound to plasma proteins.[56] Warfarin undergoes stereoselective metabolism via cytochrome P450 (CYP) 1A2, 2C9, 2C19, 2C8, 2C18, and 3A4 isoenzymes in the liver (see Fig. 26–7), with 2C9 being the main enzyme to modulate *in vivo* anticoagulant activity.[56] The pharmacokinetic parameters of warfarin, particularly hepatic metabolism, vary substantially between individuals leading to large interpatient differences in dose requirements. Genetic variations in the 2C9 isoenzyme and vitamin K epoxide reductase (VKOR) have been shown to correlate with warfarin dose requirements.[4] Given the relatively greater potency of *S*-warfarin, coadministration of drugs that induce or inhibit the CYP2C isoenzymes are more likely to cause clinically significant interactions.[4] These and other pharmacokinetic variations in warfarin metabolism likely explain the large interpatient dose-response seen with warfarin in clinical practice.

TABLE 26-13 Biologic Half-Life of Vitamin K–Dependent Coagulation Proteins

Protein	Half-Life (hours)
Prothrombin (factor II)	42–72
Factor VII	4–6
Factor IX	21–30
Factor X	27–48
Protein C	9
Protein S	60

From Wittkowsky.[98]

Dosing and Administration

The dose of warfarin is patient-specific based on the desired intensity of anticoagulation and the patient's individual response.[4] There is tremendous interpatient variability with regard to the pharmacodynamic response and pharmacokinetic disposition of warfarin. In addition, there is significant intrapatient variability in these parameters over time. Therefore, the dose of warfarin must be based on continual clinical and laboratory monitoring.[4] At the initiation of therapy, it is difficult to predict the specific dose that an individual will require. Warfarin dosing algorithms that incorporate pharmacogenetic information regarding CYP2C9 and VKOR polymorphisms are currently being evaluated. However, the clinical utility and cost-effectiveness of using pharmacogenetic information to guide warfarin initiation remains unproven.[4,57]

Although the average weekly dose of warfarin is between 25 mg and 55 mg, some patient-related variables are associated with lower than usual dose requirement, including advanced age (>65 years old), elevated baseline INR, poor nutritional status, liver disease, hyperthyroidism, genetic polymorphisms in CYP2C9 and VKOR, and concurrent use of medications known to enhance the effect of warfarin (Table 26–14).[4] Prior to initiating therapy, the clinician should screen for the presence of contraindications to anticoagulation therapy and risk factors for major bleeding (see Tables 26–8, 26–9). It is essential to collect a complete medication history, including the use of herbal and nutritional products (Tables 26–15, 26–16).

For most patients, initiating therapy with 5 mg to 10 mg daily and adjusting the dose based on the INR response will produce therapeutic INRs in 4 to 5 days (Fig. 26–8). Lower starting doses may be acceptable based on patient-related factors such as advanced age, malnutrition, liver disease, or heart failure. Starting doses >10 mg should be avoided.[4] Warfarin therapy can be safely initiated on an outpatient basis; the response to therapy should be measured

TABLE 26-14 Clinically Important Warfarin Drug Interactions

Increase Anticoagulation Effect (↑INR)	Decrease Anticoagulation Effect (↓INR)	Increase Bleeding Risk
Acetaminophen	Amobarbital	Argatroban
Alcohol binge	Butabarbital	Aspirin
Allopurinol	Carbamazepine	Clopidogrel
Amiodarone	Cholestyramine	Danaparoid
Cephalosporins (with NMTT side chain)	Dicloxacillin Griseofulvin	Dipyridamole
Chloral hydrate	Nafcillin	Unfractionated/low-molecular-weight heparin

TABLE 26-15 Warfarin Dietary Supplements Interactions Involving Cytochrome P450 Metabolism

Dietary Supplement	Mechanism
Bergamottin (component of grapefruit juice)	2C9 inhibitor
Bishop's weed (Bergapten)	3A4 inhibitor
Bitter orange	3A4 Inhibitor
Cat's claw	3A4 inhibitor
Chrysin	1A2 inhibitor
Cranberry	2C9 inhibitor
Devil's claw	2C9 Inhibitor
Dehydroepiandrosterone (DHEA)	3A4 inhibitor
Diindolymethane	1A2 inducer
Echinacea	3A4 inhibitor
Eucalyptus	3A4, 2C9, 2C19, 1A2 inhibitor
Feverfew	1A2, 2C9, 2C19, 3A4 inhibitor
Fo-ti	1A2, 2C9, 2C19, 3A4 inhibitor
Garlic	2C9, 2C19, and 3A4 inhibitor
Ginseng	CYP P450 inducer
Goldenseal	3A4 inhibitor
Guggul	3A4 inducer
Grape	1A2 inducer
Grapefruit juice	1A2, 2A6, and 3A4 inhibitor
Indole-3-carbinol	1A2 Inducer
Ipriflavone	2C9, 1A2 inhibitor
Kava	1A2, 2C9, 2C19, 2D6, 3A4 inhibitor
Licorice	3A4 inhibitor
Lime	3A4 inhibitor
Limonene	2C9, 2C19 substrate, and 2C9 inducer
Lycium (Chinese wolfberry)	2C9 inhibitor
Milk thistle	2C9 and 3A4 inhibitor
Peppermint	1A2, 2C9, 2C19, 3A4 inhibitor
Red clover	1A2, 2C9, 2C19, 3A4 inhibitor
Resveratrol	1A, 2E1 3A4 inhibitor
St. John's wort	1A2, 2C9, 3A4 inducer
Sulforaphane	1A2 inhibitor
Valerian	3A4 inhibitor
Wild cherry	3A4 inhibitor

From Nutescu et al.[63]

every 1 to 3 days until stabilized. For patients with acute venous thrombosis, UFH, LMWH, or fondaparinux should be overlapped with warfarin therapy for at least 5 days regardless of whether the target INR has been achieved earlier.[6]

When adjusting the dose of warfarin, the clinician should allow sufficient time for changes in the INR to occur. In general, maintenance dose changes should not be made more frequently than every 3 days. Doses should be adjusted by calculating the weekly dose and reducing or increasing the weekly dose by 5% to 25%. The effect of dose changes may not become evident for 5 to 7 days. During maintenance therapy, patients should not have follow-up INR tests sooner than anticipated changes are likely to occur.[4]

Therapeutic Monitoring

Warfarin requires frequent laboratory monitoring to ensure optimal therapeutic outcomes and minimize bleeding complications. The prothrombin time has been used for decades to monitor the anticoagulation effects of warfarin. The PT measures the biologic activity of factors II, VII, and X activity and correlates well to warfarin's anticoagulation effect. The test is performed by measuring the time required for clot formation after adding calcium and thromboplastin to citrated plasma.[4] Several thromboplastins, varying in responsiveness to reductions in vitamin K-dependent clotting factors are commercially available. The PT is problematic to interpret because the variable sensitivity of thromboplastin reagents. With a given blood sample, thromboplastins of differing sensitivity will produce substantially different results some of which could lead to inappropriate dosing decisions. The World Health Organization (WHO) addressed the need for standardization in the late 1970s by developing a reference thromboplastin and recommending the use of the INR to monitor warfarin therapy. The INR corrects for differences in thromboplastin reagents through the following formula:

$$\mathrm{INR} = \left(\frac{\mathrm{PT}^{\mathrm{Patient}}}{\mathrm{PT}^{\mathrm{Control}}}\right)^{\mathrm{ISI}}$$

TABLE 26-16 Dietary Supplements That Can Affect Platelet Function and Anticoagulation Status

Agent	Mechanism	Comments
Bladderwrack	Has anticoagulant effects	Increased risk of bleeding or bruising
Boldo	Constituents may have antiplatelet effects	Increased risk of bleeding or bruising
Bromelain	Decreased platelet aggregation	Increased risk of bleeding or bruising
Burdock	Decreased platelet aggregation by inhibiting platelet activation factor	Increased risk of bleeding or bruising
Caffeine	May have antiplatelet activity; not reported in humans	Increased risk of bleeding or bruising; found in black tea, green tea, guarana, mate, oolong tea
Clove	Eugenol has antiplatelet activity	Increased risk of bleeding or bruising
Cod liver oil	May inhibit platelet aggregation	Increased risk of bleeding or bruising; avoid concomitant use
Coltsfoot	May inhibit platelet aggregation	Increased risk of bleeding or bruising; avoid concomitant use
Danshen	Decreased platelet aggregation; may also have antithrombotic effects	Increased risk of bleeding or bruising; avoid concomitant use
Dong quai	May inhibit platelet aggregation	Increased risk of bleeding or bruising
Fenugreek	Constituents may have antiplatelet effects; concentration may not be clinically significant	Increased risk of bleeding or bruising
Fish oil	Has antiplatelet effects	Increased risk of bleeding or bruising
Flax seed	Decreased platelet aggregation and increased bleeding time	Increased risk of bleeding or bruising
Gamma linolenic acid (GLA)	Has anticoagulant effects	Increased risk of bleeding or bruising; found in borage and evening primrose oil
Garlic	Has anticoagulant effects and may inhibit platelet aggregation	Increased risk of bleeding or bruising
Ginger	Inhibit thromboxane synthetase and decrease platelet aggregation	Increased risk of bleeding or bruising
Ginkgo	Decreased platelet aggregation; ginkgolide B, a component of ginkgo, is a potent inhibitor of PAF	Increased risk of bleeding or bruising
Ginseng, panax	Components may decrease platelet aggregation through PAF antagonism; not shown in humans	Increased risk of bleeding or bruising; use with caution until more is known.
Ginseng, Siberian	A component, dihydroxybenzoic acid, may inhibit platelet aggregation	Increased risk of bleeding or bruising
Melatonin	Unknown; might increase the anticoagulant or antiplatelet effect; decreased prothrombin activity observed	Increased risk of bleeding or bruising
Nattokinase	Has thrombolytic activity	Increased risk of bleeding or bruising
Onion	Decreased platelet aggregation	Increased risk of bleeding or bruising
Pantethine	Decreased platelet aggregation	Increased risk of bleeding or bruising
Policosanol	Inhibits platelet aggregation	Increased risk of bleeding or bruising
Poplar	Contains salicylates and may cause decreased platelet aggregation	Increased risk of bleeding or bruising
Resveratrol	Has antiplatelet effects	Increased risk of bleeding or bruising
Sea buckthorn	Inhibits platelet aggregation	Increased risk of bleeding or bruising
Turmeric	Decreased platelet aggregation; has antiplatelet effects	Increased risk of bleeding or bruising
Vinpocetine	Has antiplatelet effects	Increased risk of bleeding or bruising
Vitamin E	Inhibits platelet aggregation and antagonizes the effects of vitamin K–dependent clotting factors	Dose dependent and significant with doses greater than 800 units per day; advise patients to avoid high doses of vitamin E; increased risk of bleeding or bruising
Willow bark	Decreased platelet aggregation; has antiplatelet effects but less than aspirin	Increased risk of bleeding or bruising

PAF, platelet-activating factor.
From Nutescu et al.[63]

The International Sensitivity Index (ISI) is a measure of the thromboplastin's responsiveness compared to the WHO reference standard.[4] Each thromboplastin reagent manufactured has an ISI value that should be used to calculate the INR. Although the INR system has a number of potential problems, it is currently the best means available to interpret the PT and the preferred method for monitoring oral anticoagulation therapy.

The recommended target INR and associated goal range is based on the therapeutic indication.[4] For most indications, the target INR is 2.5 with an acceptable range of 2.0 to 3.0. The target INR is higher for some patients with mechanical prosthetic heart valves (target INR, 3.0; range, 2.5–3.5).[4] A baseline PT and complete blood cell count should be obtained prior to initiating warfarin therapy. In patients with an acute thromboembolic event, an INR should be measured minimally every 3 days during the first week of therapy (daily INRs are common in hospitalized patients). Once the patient's dose-response is established, an INR should be determined every 7 to 14 days until it stabilizes and optimally every 4 to 8 weeks thereafter.[4,58]

At each encounter, patients should be meticulously questioned regarding their medication use and symptoms related to bleeding and thromboembolic complications. Any changes in medications, including changes in dose as well as non-prescription drug and dietary supplement use, should be carefully explored (see Tables 26–14, 26–15, 26–16). Dietary intake of vitamin K rich foods should also be evaluated (Table 26–17).

Anticoagulation therapy management services can improve the care of patients who take warfarin therapy by providing structured, comprehensive patient education and evaluation.[4] When staffed by experienced and knowledgeable practitioners, anticoagulation management services improve the safety and effectiveness of warfarin therapy compared to "usual" medical care.[59] Anticoagulation patient management services lower the overall cost of care by reducing the frequency of major bleeding and recurrent thromboembolic events.[59]

Portable finger stick INR devices are available for monitoring warfarin therapy. These devices permit clinicians to do "real-time" therapeutic drug monitoring, and enable patients to engage in self-testing at home.[60] Self-monitoring, in its simplest form, requires the patient to report their test results to a healthcare professional. In such arrangements, the clinician continues to make warfarin dosing decisions. Highly motivated and sophisticated patients can be trained to manage themselves, independently altering the dose of

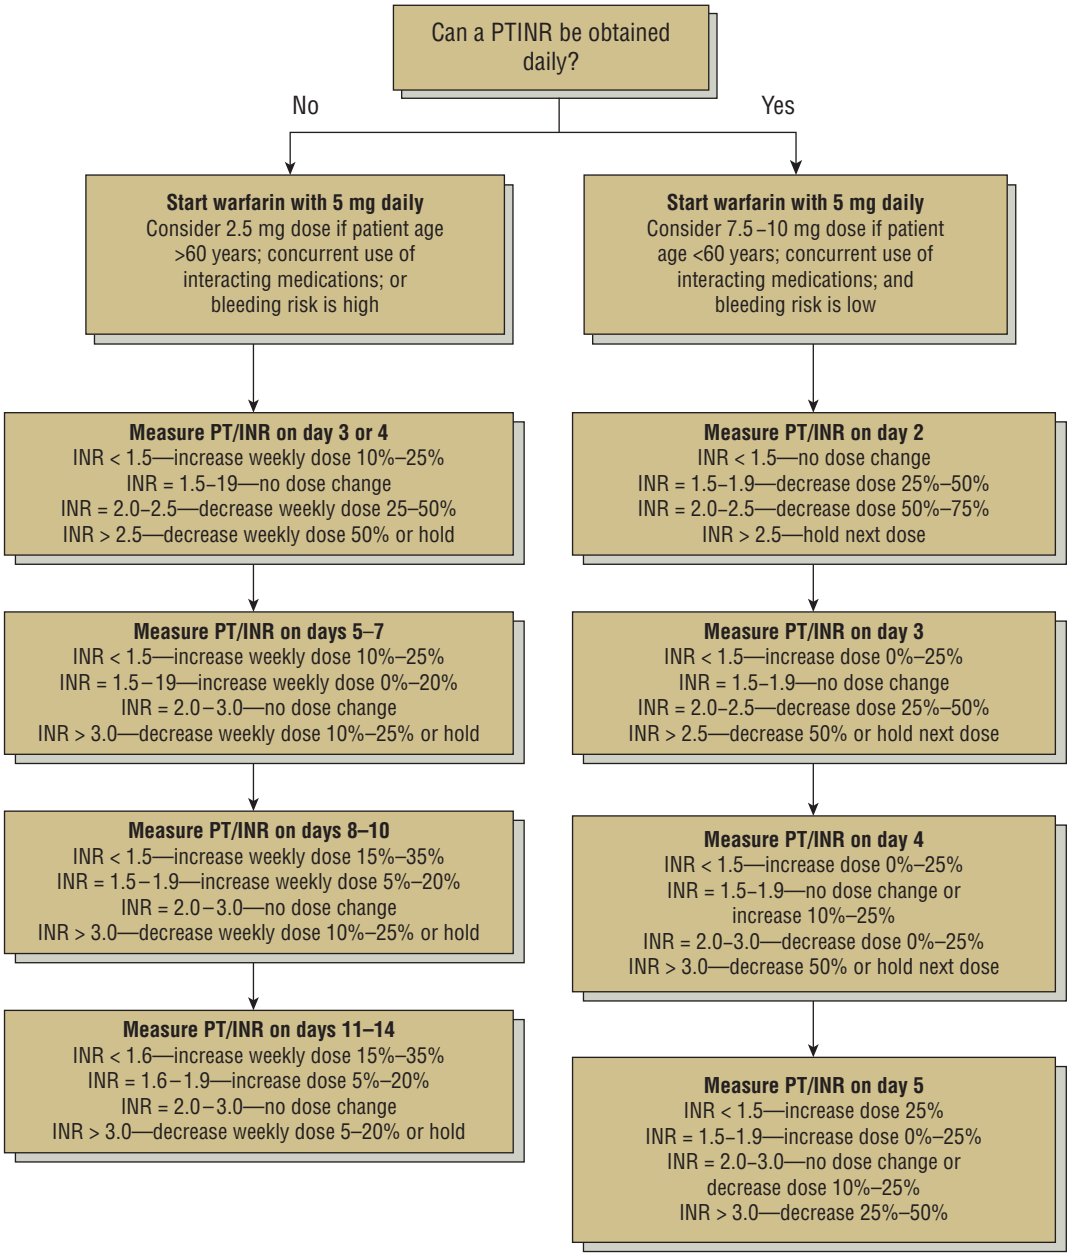

FIGURE 26-8. Initiation of warfarin therapy. (INR, international normalized ratio; PT, prothrombin time.)

warfarin therapy based on their INR results. Patients who engage in INR self-monitoring and warfarin self-management report high levels of satisfaction with care and maintain the INR within the therapeutic range more frequently than those managed by "usual care."[60] Home INR testing and self management are clearly not for everyone, however. These modalities require careful patient selection and considerable education. Finger stick INR devices are relatively expensive, but some Medicare patients may qualify for limited coverage of the monitor and testing strips.

Adverse Effects

Warfarin's primary adverse effect is bleeding.[3] Hemorrhagic complications, ranging from mild to life-threatening, can occur at any site in the body. Although warfarin is not believed to cause bleeding per se, it can "unmask" bleeding from an existing lesion or enable massive bleeding from an ordinarily minor source. The gastrointestinal tract and the nose are the most frequent sites of bleeding. Intracranial hemorrhage is the most serious and feared complication related to warfarin therapy, often resulting in permanent disability or death.[3]

The annual incidence of major bleeding ranges from 1% in highly selected patient populations who are carefully managed, to greater than 10% in patients managed in less-structured environments.[3,4] There are no universally accepted criteria for defining a bleeding event as major or minor. Most studies have defined major bleeding as any bleeding into a critical anatomic space (e.g., intracranial bleeding, hemarthrosis, or intraocular bleeding), bleeding that requires transfusion of 2 or more units of blood or plasma, or that leads to a greater than 2 g/dL drop in hemoglobin concentration. Bleeding that does not meet the criteria for a major hemorrhage is generally considered to be a minor. Minor bleeding is common during warfarin therapy. Few studies have prospectively evaluated the incidence of minor bleeding but it is likely to be greater than 15% annually even in the most expertly managed patients.[3,4]

Several risk factors for bleeding while taking anticoagulation therapy have been identified (see Table 26–8).[3,4] Intensity of

TABLE 26-17 Vitamin K Content of Select Foods[a]

Very High (>200 mcg)	High (100–200 mcg)	Medium (50–100 mcg)	Low (<50 mcg)
Brussel sprouts	Basil	Apple, green	Apple, red
Chickpea	Broccoli	Asparagus	Avocado
Collard greens	Chive	Cabbage	Beans
Coriander	Coleslaw	Cauliflower	Breads, grains
Endive	Cucumber (with peel)	Mayonnaise	Carrot
Kale	Canola oil	Nuts, pistachio	Cereal
Lettuce, red leaf	Green onion/scallion	Squash, summer	Celery
Parsley	Lettuce, butterhead		Coffee
Spinach	Mustard greens		Corn
Swiss chard	Soybean oil		Cucumber (without peel)
Tea, green			Dairy products
Tea, black			Eggs
Turnip greens			Fruit (varies)
Watercress			Lettuce, iceberg
			Meats, fish, poultry
			Pasta
			Peanuts
			Peas
			Potato
			Rice
			Tomato

[a] Approximate amount of vitamin K per 100 g (3.5 oz) serving.
From Booth and Centurelli.[99]

anticoagulation therapy appears to be the most powerful risk factor. Patients whose target INR is greater than 3.0 have twice the incidence of major bleeding compared to those with a target of 2.5. The risk of intracranial hemorrhage increases significantly when the INR remains greater than 4.0 for prolonged periods of time especially in the elderly. Unstable INR control also appears to be associated with an increased risk of bleeding. The risk of hemorrhage is greatest during the first few weeks of therapy; however, bleeding can occur at any time and the cumulative incidence steadily increases over time.[3,4]

Nonhemorrhagic adverse effects associated with warfarin are uncommon, but can be serious when they do occur.[4] The "purple toe syndrome," manifested as a purplish discoloration of the toes, is an extremely rare event reported in a small percentage of patients receiving warfarin. The etiology of this unusual phenomenon is unknown, but is thought to be the result of cholesterol microembolization into the arterial circulation of the toes.[56]

Warfarin-induced skin necrosis is an uncommon but very serious dermatologic reaction that is manifested by a painful maculopapular rash and ecchymosis or purpura that subsequently progresses to necrotic gangrene. It most frequently appears in areas of the body rich in subcutaneous fat, such as the breasts, thighs, buttocks, and abdomen. The incidence of warfarin-induced skin necrosis is less than 0.1%.[61] It occurs most commonly in middle-aged women who are being treated for acute venous thrombosis. Although symptoms generally appear during the first week of therapy, it has been reported in a small number of patients who had taken warfarin for months and even years. The pathogenesis of warfarin-induced skin necrosis is not clearly understood. Many believe imbalances between procoagulant and anticoagulant proteins that occur early in the course of warfarin therapy resulting in capillary thrombosis and secondary hemorrhages. The observation that patients with proteins C or S deficiency appear to be at greater risk for warfarin-induced skin necrosis supports this theory. Warfarin-induced skin necrosis has also been reported in patients with other disorders of hypercoagulability, such as antithrombin deficiency and antiphospholipid antibodies. Patients who receive large "loading" doses of warfarin may also be at greater risk.[61] Overlapping warfarin and injectable anticoagulants is especially important in any patient suspected to have a hypercoagulable state or who has a strong family history of venous thrombosis. If the diagnosis of skin necrosis is suspected, warfarin therapy should be immediately discontinued, fresh-frozen plasma and vitamin K administered, and full-dose UFH or LMWH therapy initiated. Warfarin therapy should be restarted in patients with a history of skin necrosis with extreme caution using small doses and gradual titration until therapeutic INR has been achieved, if at all.[61]

Management of Bleeding and Excessive Anticoagulation

Specific recommendations for the management of patients with an elevated INR are published by the American College of Chest Physicians (ACCP) Consensus Conference on Antithrombotic Therapy.[4] Patients with a mildly elevated INR (3.5–5.0) should be examined for signs and symptoms of bleeding, as well as factors that increase bleeding risk. In this circumstance, either reducing the dose of warfarin or holding one or two doses will safely manage most patients. When a swift reduction in an elevated INR is required, oral or intravenous vitamin K_1 (phytonadione) can be given. In the absence of major bleeding, the oral route of administration is preferred. While the IV route produces a more rapid reversal, previous parenteral formulations have been associated with rare but serious anaphylactoid reactions. The risk of this reaction can be reduced with slow infusion of diluted vitamin K solution. If the INR is between 5 and 9 and no bleeding is present, doses of warfarin should be withheld and may be combined with a low dose of oral vitamin K (≤2.5 mg). Administering vitamin K in this situation will increase both the rate of INR decline and the potential for INR overcorrection; however, neither of these outcomes has been shown to affect the risk of developing subsequent bleeding or thromboembolism compared to simply withholding warfarin alone.[62] Therefore, the decision to administer vitamin K should be individualized based on the patient's bleeding risk and the underlying indication for anticoagulation therapy (see Fig. 26–9). Vitamin K should be used with caution in patients at high risk of recurrent thromboembolism because of the possibility of INR overcorrection. Conversely, simply withholding warfarin therapy may not lower a high INR quickly

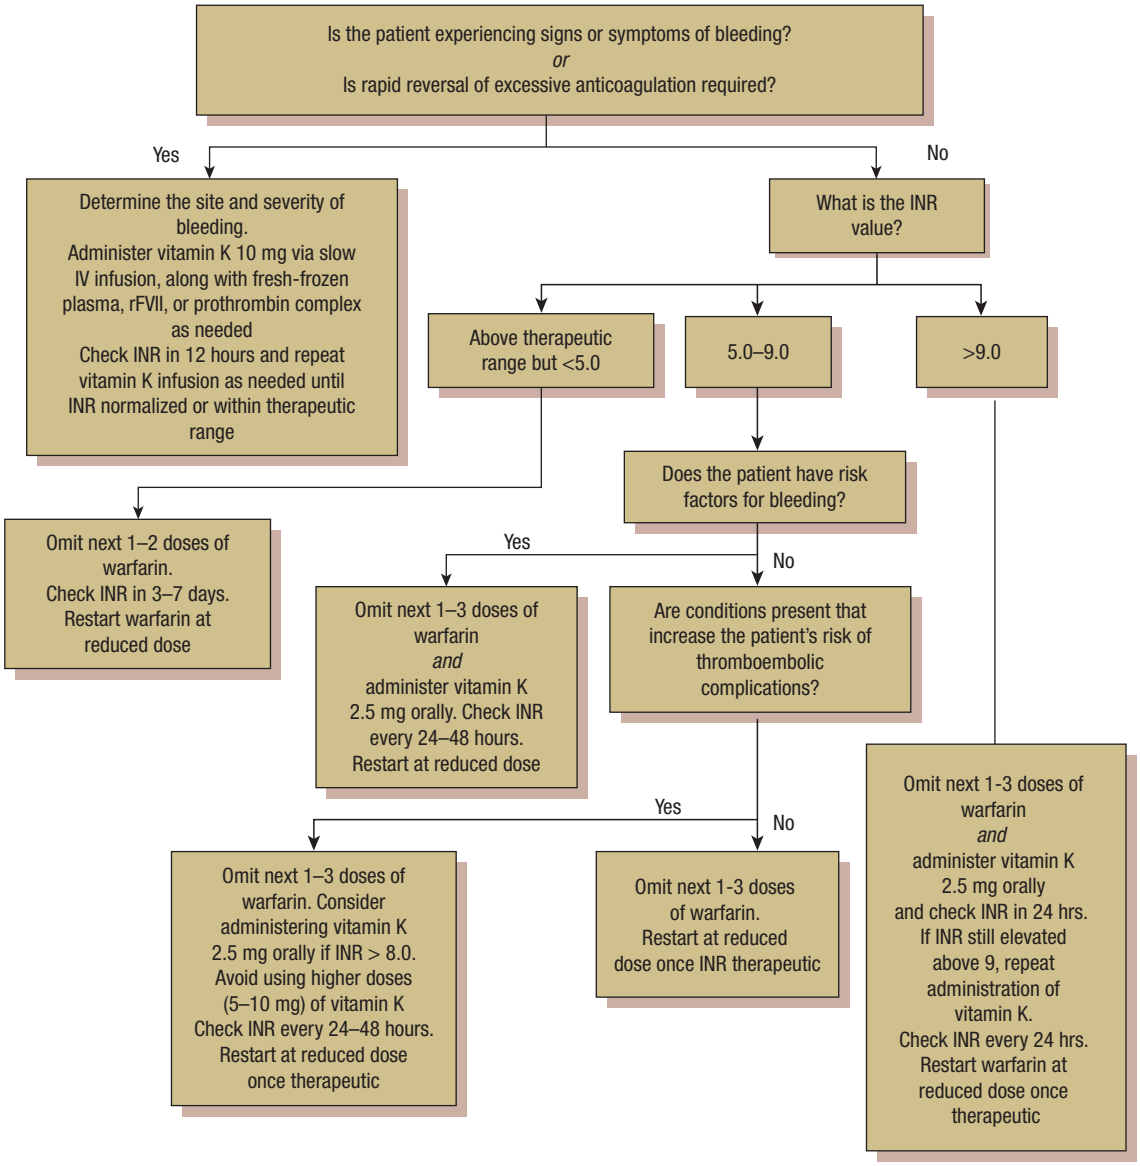

FIGURE 26-9. Management of an elevated international normalized ratio (INR) in patients taking warfarin. Dose reductions should be made by determining the weekly warfarin dose and reducing the weekly dose by 10% to 25% based on degree of INR elevation. Conditions that increase the risk of thromboembolic complications include history of hypercoagulability disorders (e.g., protein C or S deficiency, presence of antiphospholipid antibodies, antithrombin deficiency, activated protein C resistance), arterial or venous thrombosis within the previous month, thromboembolism associated with malignancy, and mechanical mitral valve in conjunction with atrial fibrillation, previous stroke, poor ventricular function, or coexisting mechanical aortic valve. (INR, international normalized ratio; rFVII, recombinant factor VII.)

enough in patients at high risk for developing bleeding complications. Most patients with asymptomatic INR elevations can be safely managed by withholding warfarin alone. If the INR is greater than 9, 2.5 mg to 5mg of oral vitamin K is recommended.[4] High doses of vitamin K (e.g., 10 mg) are associated with prolonged resistance to warfarin and the occurrence of thromboembolic complications and should only be administered to patients with serious bleeding. In the event of a serious or life-threatening bleeding, intravenous vitamin K should be administered as well as fresh-frozen plasma, clotting factor concentrates, or recombinant FVII.[4]

Drug–Drug and Drug–Food Interactions

The pharmacokinetic and pharmacodynamic properties of warfarin, coupled with its narrow therapeutic index, predispose this agent to numerous clinically important food and drug interactions (see Tables 26–14, 26–15, 26–16, 26–17).[4,56] Vitamin K can reverse warfarin's pharmacologic activity, and many foods contain sufficient vitamin K to reduce the anticoagulation effect of warfarin if a patient consumes them in large portions or repetitively within a short period of time.[63] Patients should be given a list of vitamin K-rich foods and instructed to maintain a relatively consistent intake. It is important to stress consistency and moderation rather than absolute abstinence. Abrupt changes in vitamin K intake should be considered when unexplained changes in the INR occur.[64] Alternative sources of vitamin K, such as multivitamins and nutritional supplements (e.g., Sustacal and Ensure) should also be considered. Patients who require parenteral nutrition should not receive a weekly bolus dose of vitamin K if they are taking warfarin therapy.

Pharmacokinetic drug interactions with warfarin are primarily a result of alterations in hepatic metabolism or binding to plasma proteins. Drugs that inhibit or induce the CYP2C9, CYP1A2, and

CYP3A4 isoenzymes have the greatest potential to significantly alter the response to warfarin therapy.[4] Protein-binding displacement interactions can also occur. However, in the absence of hepatic disease or a diminished capacity to metabolize warfarin, changes in protein binding result in only transient changes in the INR. Drugs that alter hemostasis, platelet function, or the clearance of clotting factors (e.g., thyroid hormone replacement) can alter the response to warfarin therapy or increase the risk of bleeding by pharmacodynamic mechanisms.[4]

The explosive increase in the use of herbal and alternative therapies in North America has raised concern regarding their potential to interact with warfarin therapy.[63] All patients on warfarin therapy should be questioned regarding the use of herbal drugs and dietary supplements. Clinicians should advise patients on warfarin therapy to seek information about potential interactions with warfarin whenever they start to take a new drug product, whether it is prescribed or purchased over the counter. If there is a known drug interaction or doubt about its potential to alter the response to warfarin, more frequent INR testing following the initiation of the new agent is prudent.[4]

Use in Special Populations

In the absence of a clear and compelling indication, warfarin should not be used during pregnancy because of the potential for fetal hemorrhage and teratogenic complications.[16] Warfarin crosses the placenta and is associated with several embryopathies, particularly CNS abnormalities that have occurred throughout gestation. The FDA has designated warfarin a pregnancy category X agent.[56] As UFH and the LMWHs are large molecules that do not cross the placental barrier, they are considered the drugs of choice for anticoagulation during pregnancy.[16] Warfarin is excreted into the breast milk in very low concentrations[56] and is generally considered safe to use by women who are breastfeeding.

Patients scheduled to undergo major surgery or other invasive procedures often require temporary discontinuation of warfarin therapy.[65] The decision to withhold warfarin therapy should be based on the type of surgical procedure being performed and the patient's risk of bleeding and thromboembolism. Warfarin therapy should generally not be discontinued in patients undergoing minimally invasive procedures such as dental work.[65] If the bleeding risk from the procedure is considerable, warfarin should be stopped 4 to 5 days prior to the procedure in order to allow the INR to return to near-normal values. Alternatively, warfarin can be stopped and a low dose (1–2 mg) of oral vitamin K may be given 1 to 2 days prior to the procedure.[65] Patients at high risk of thromboembolism (i.e., DVT or PE in the previous month) should be given so-called bridge therapy with UFH or a LMWH before and/or after the procedure (Table 26–18).

Warfarin use among elderly patients is increasingly common. Although the drug has been extensively studied in this population, some debate still remains regarding the relative risks of warfarin therapy in the elderly.[4] Accumulating evidence indicates that increasing age is an independent risk factor for major bleeding during anticoagulation therapy.[3] Age >75 years is associated with an increased risk of intracranial hemorrhage, especially when the INR is supratherapeutic.[3] Elderly patients may be more prone to excessive anticoagulation as a consequence of nutritional deficiencies, comorbidities, and multiple drug interactions. However, age >70 has also been associated with an increased likelihood of achieving stable INR control.[58] The elderly are often at greater risk of falls. Although they often derive the greatest benefit from anticoagulation therapy, elderly patients should be monitored with greater vigilance, and warfarin dose changes should be made more cautiously.

TABLE 26-18 General Approach to Periprocedural Anticoagulation Therapy Management

Days Relative to Procedure	Anticoagulation Management
−7 to −10	Assess thrombosis and bleeding risk Determine appropriate bridging plan Obtain baseline INR
−7	Stop aspirin or other antiplatelet therapy if necessary
−6 or −5	Stop warfarin[a]
−4 or −3	Start LMWH[b]
−2	LMWH
−1	Give last dose of LMWH 24 h before procedure[c] Obtain INR
0 = Procedure	Resume warfarin[d] at usual maintenance dose on evening after procedure
+1	Resume LMWH[e] Resume aspirin or other antiplatelet therapy once hemostasis secured Warfarin
+2 to + 3	LMWH[e] Warfarin Obtain INR and CBC
+4 to +5	LMWH Warfarin Obtain INR and CBC
<+6	Stop LMWH once INR is therapeutic

[a] Warfarin stopped on day −5 if baseline INR 2.0 to 3.0 or day −6 if baseline INR is 2.5 to 3.5.
[b] LMWH is initiated 2 days (36–48 h) after warfarin is discontinued.
[c] Give only the morning dose of twice-daily therapeutic-dose LMWH and reduce by 50% the total dose of once-daily therapeutic-dose LMWH.
[d] Some clinicians instruct patients to take "booster" doses (e.g., 150% of usual dose) for 1 to 2 days when resuming warfarin therapy.
[e] Resume therapeutic-dose LMWH approximately 24 h after (e.g., the day after) the procedure for minor surgical or other invasive procedures; for major surgery or high bleeding risk procedures wait 48 to 72 h after the procedure and when hemostasis is secured before resuming therapeutic-dose LMWH, *or* administer prophylactic-dose LMWH when hemostasis is secured, *or* avoid LMWH completely.
CBC, complete blood count; INR, international normalized ratio; LMWH, low-molecular-weight heparin.

GENERAL APPROACH TO THE PREVENTION OF VENOUS THROMBOEMBOLISM

Given that VTE is potentially fatal and costly to treat, strategies to prevent DVT in at-risk populations will have the greatest impact on patient outcomes.[2,8,66] To rely on the early diagnosis and treatment of VTE is unacceptable because many patients will die before treatment can be initiated. Despite an immense body of literature that overwhelmingly supports the widespread use of pharmacologic and mechanical strategies to prevent VTE, prophylaxis is underused in many hospitals. Even when prophylaxis is given, many patients receive prophylaxis that is less than optimal. Educational programs and clinical decision support systems have been shown to improve the appropriate use of VTE prevention methods.

5 The goal of an effective VTE prophylaxis program is to identify all patients at risk, determine each patient's level of risk, select and implement regimens that provide sufficient protection for the level of risk, and avoid or limit complications from the selected regimens. As hospitalized patients are frequently at high risk for VTE, screening all patients prior to or at the time of admission to determine their level of risk is the first step in an effective VTE prevention program.[2] The risk classification criteria and suggested prophylaxis strategies published by the ACCP Clinical Practice Guidelines and the Surgical Care Improvement Project

(SCIP) are widely used (Table 26–19). Several pharmacologic and mechanical methods are effective for preventing VTE, and these can be used alone or in combination. Mechanical methods improve venous blood flow, whereas drug therapy counteracts the propensity for thrombus formation by inhibiting the coagulation cascade.

MECHANICAL STRATEGIES

Resumption of ambulation as soon as possible following surgery reduces the incidence of VTE in low-risk patients.[2] Walking increases venous blood flow and promotes the flow of natural antithrombotic factors into the lower extremities. During prolonged surgeries, venous foot pumps that mimic the pumping action produced during ambulation can be beneficial.

Graduated compression stockings reduce the incidence of VTE by approximately 60% following general surgery, neurosurgery, and stroke.[2] Compression stockings work by increasing the velocity of venous blood flow through the application of graded pressure, with the greatest amount applied at the ankle. This treatment option is inexpensive and safe, and an excellent choice when pharmacologic intervention is either contraindicated or difficult to adequately monitor. When combined with pharmacologic interventions, graduated compression stockings have an additive effect. However, compression stockings can be uncomfortable and some patients are unable to wear them because of the size or shape of their legs.

Intermittent pneumatic compression (IPC) devices increase the velocity of blood flow in the lower extremities.[2] The technique involves the sequential inflation of a series of cuffs wrapped around the patient's legs. The cuffs use graded pressure and inflate in 1- to 2-minute continuous cycles from the ankles to the thighs. IPC reduces the risk of VTE by more than 60% following general surgery, neurosurgery, and orthopedic surgery.[2] There is some theoretical concern that external compression may dislodge a previously formed clot. Although IPC is well tolerated and safe to use in patients who have contraindications to pharmacologic therapies, it does have drawbacks. It is more expensive than the use of graduated compression stockings; it is a relatively cumbersome technique; and some patients have difficulty sleeping while using it. Compliance with IPC use throughout the day is relatively poor in many hospitals, leaving patients without effective thromboprophylaxis. Like graduated compression hose, IPC can be used in combination with pharmacologic strategies.

Inferior vena cava (IVC) filters can provide short-term protection against PE in very high-risk patients by preventing the embolization of a thrombus formed in the lower extremities into the pulmonary circulation.[2] Percutaneous insertion of a filter into the IVC is a minimally invasive procedure performed via fluoroscopy. Despite the widespread use of IVC filters, there are limited data regarding their effectiveness and long-term safety. The evidence suggests that IVC filters, particularly in the absence of effective antithrombotic therapy, increase the long-term risk of recurrent DVT.[67] Although IVC filters can reduce the short-term risk of PE in patients who are at highest risk, they should be reserved for patients in whom other prophylactic strategies cannot be used. To reduce the long-term risk of DVT associated with IVC filter use, pharmacologic prophylaxis is needed. Anticoagulation therapy should begin as soon as the patient is able to tolerate it.

PHARMACOLOGIC STRATEGIES

Numerous pharmacologic options have been extensively evaluated in randomized clinical trials (see Table 26–19).[2,68] Appropriately selected drug therapies can significantly reduce the incidence of VTE following hip and knee replacement, hip fracture repair, general surgery, myocardial infarction, and ischemic stroke. The choice of agent and dose to use for VTE prevention must be based on the patient's level of risk for thrombosis and bleeding complications, as well as cost and availability.

The most extensively studied agents for the prevention of VTE are UFH, the LMWHs, and fondaparinux.[2,68] The LMWHs and fondaparinux provide superior protection against VTE when compared with low-dose UFH. Their more predictable absorption when given by subcutaneous injection may be the explanation. Even so, UFH remains an effective, cost-conscious choice for many patient populations, provided that it is given in the appropriate dose. Low-dose UFH (5,000 units every 12 hours or every 8 hours) given subcutaneously reduces the risk of VTE by 55% to 70% in patients undergoing a wide range of general surgical procedures and following myocardial infarction or stroke. For the prevention of VTE following hip and knee replacement surgery, the effectiveness of low-dose UFH is considerably lower. The LMWHs and fondaparinux appear to provide a high degree of protection against VTE

TABLE 26-19 DVT Risk Classification and Suggested Prevention Strategies

Level of Risk	Risk of DVT without Thromboprophylaxis	Suggested Prevention Strategies
Low		
Patients undergoing minor surgery and fully ambulatory	<10%	Early and aggressive ambulation
Patients who are medically ill and fully ambulatory		
Moderate		
Most patients undergoing general, gynecological, or urological surgeries	10–40%	UFH 5,000 units SC q 8 or 12 h
Most patients who are hospitalized for an acute medical illness (e.g., MI, ischemic stroke, CHF exacerbation, acute respiratory illness)		LMWH (at recommended dose) Fondaparinux
Patients who are at moderate DVT risk and high risk for bleeding		Mechanical thromboprophylaxis[a]
High		
Patients undergoing major lower-extremity orthopedic surgery (hip or knee arthroplasty, hip fracture repair)	40–80%	LMWH (at recommended dose) Fondaparinux Warfarin (INR goal = 2.0–3.0)
Spinal cord injury		Oral factor Xa inhibitors[b] Oral direct thrombin inhibitors[b]
Major trauma		Mechanical thromboprophylaxis[a]
Patients who are at high DVT risk and high risk for bleeding		

[a] Mechanical thromboprophylaxis includes intermittent pneumatic compression (IPC), graduated compression stockings (GCS), and venous foot pumps (VFP)

[b] Oral factor Xa inhibitors and oral direct thrombin inhibitors are investigational agents. These agents have not yet been formally endorsed as appropriate VTE prevention strategies in clinical practice guidelines.

DVT, deep vein thrombosis; CHF, congestive heart failure; INR, international normalized ratio; MI, myocardial infarction; UFH, unfractionated heparin.

Adapted from Geerts et al.[2]

in most high-risk populations. The appropriate prophylactic dose for each LMWH product is indication specific (see Table 26–10). There is no evidence that one LMWH is superior to another for the prevention of VTE. Fondaparinux was significantly more effective than enoxaparin at preventing venographically detected DVT and proximal DVT in several clinical trials that enrolled patients undergoing high risk orthopedic procedures but has not shown superiority in reducing the incidence of symptomatic PE or mortality. Fondaparinux has also been show to cause more bleeding than enoxaparin when administered within 6 hours of orthopedic surgery.[2] To provide optimal protection, some experts believe that the LMWHs should be initiated prior to surgery.[2]

Warfarin is a commonly used option for the prevention of VTE following orthopedic surgeries of the lower extremities.[2] The evidence is equivocal regarding the relative effectiveness of warfarin compared to the LMWHs for the prevention of clinically important VTE events in the highest risk populations. When used to prevent VTE, the dose of warfarin should be adjusted to maintain an INR between 2.0 and 3.0; however, some orthopedic surgeons favor lower initial INR goal ranges (e.g., 1.5–2.5) because of fear of bleeding at the surgical site. Oral administration and low drug cost give warfarin some advantages over LMWHs and fondaparinux. However, warfarin does not achieve its full antithrombotic effect for several days, requires frequent monitoring and periodic dosage adjustments, and carries a substantial risk of major bleeding. Furthermore, warfarin should be recommended only when a well-coordinated monitoring system is available.[4]

The optimal duration for VTE prophylaxis following surgery is not well established.[2] Prophylaxis should be given throughout the period of risk. For general surgical procedures and medical conditions, once the patient is able to ambulate regularly and other risk factors are no longer present, prophylaxis can be discontinued. Because of the relatively high incidence of VTE in the first month following hospital discharge among patients who have undergone a lower extremity orthopedic procedure, extended prophylaxis following hospital discharge with either LMWH, fondaparinux, or warfarin appears to be beneficial. Most clinical trials support the use of antithrombotic therapy for 21 to 35 days following total hip replacement and hip fracture repair surgeries.[2,68]

Given the limitations of warfarin, there has been considerable interest in alternative medications and several new oral agents are in various stages of development.[69] New oral anticoagulants hold the promise of fixed dosing, rapid onset, fewer drug–drug interactions, and simplified monitoring requirements.[70] A few of these agents, specifically rivaroxaban, apixaban, and dabigatran, have been evaluated in phase 3 clinical trials for use in high-risk populations for the prevention of VTE. In patients who have undergone elective knee or hip replacement placement, these new agents appear to be comparable or superior to enoxaparin in terms of efficacy and safety. To date, none of these agents have been compared with warfarin in the setting of VTE prevention. While the results of initial clinical trials have been favorable, they should be viewed with caution until postmarketing studies are completed, providing a greater sense of the potential value of these new agents in a variety of patient populations.

PHARMACOECONOMIC CONSIDERATIONS

Only a handful of studies have formally evaluated the cost-effectiveness of VTE prevention strategies. The acquisition costs of graduated compression stockings, UFH, and warfarin are considerably less than those of LMWH and fondaparinux. However, the acquisition cost for drug therapy is relatively small when compared with the overall cost of care.[66] Economic analyses must take into account the efficacy of the strategy, duration of use, complications, and monitoring costs.[71,72]

The determination of the cost-effectiveness of VTE prophylaxis is based on the premise that a reduction in future VTE events will reduce overall healthcare costs.[71] Furthermore, the incremental cost per patient will decrease proportionally with increasing frequency of VTE in the population. Stated another way, the cost of providing prophylaxis to 1,000 patients will decline as the incidence of VTE in the given population increases. Consequently, more expensive and effective strategies become more cost-effective in higher-risk populations. In populations at low risk for VTE, early ambulation appears to be the most cost-effective strategy. Although LMWH provides slightly greater reductions in the risk of VTE in patients who are at moderate risk of VTE, the additional cost is estimated to be $107 (in 1999 dollars) per patient when compared to low-dose UFH.[73] Whether universal use of LMWH in moderate-risk patients is a cost-effective strategy is controversial.

In high-risk patients, the cost-effectiveness of prevention is far greater because the incidence of VTE is higher.[71] Following hip replacement surgery, regardless of the strategy selected, prophylaxis saves money when compared with no prophylaxis. LMWHs and fondaparinux slightly increase the total mean cost of care after total hip and knee replacement when compared with low-dose UFH and warfarin.[74] However, because of their superior effectiveness, LMWH and fondaparinux have a significantly lower cost per DVT and PE avoided. Based on typical drug-acquisition costs, LMWH and fondaparinux are generally considered cost-effective choices in the highest-risk patient populations.

GENERAL APPROACH TO THE TREATMENT OF VENOUS THROMBOEMBOLISM

6 Before initiating anticoagulation therapy for the treatment of VTE, it is imperative to establish an accurate diagnosis; thus preventing unnecessary risk and expense to the patient. Anticoagulation therapy remains the mainstay of treatment for VTE. DVT and PE are manifestations of the same disease process and are treated similarly.[6] Full "therapeutic" doses of antithrombotic drugs prevent thrombus extension and embolization as well as reduce the risk of long-term sequelae such as the postthrombotic syndrome, chronic thromboembolic pulmonary hypertension, and recurrent thromboembolism.[6] The standard approach is to initiate therapy with an injectable anticoagulant and to make the transition to warfarin for maintenance therapy (Table 26–20 and Fig. 26–10). Determining the optimal duration of anticoagulation involves weighing the risk of recurrent VTE against the risk of bleeding associated with anticoagulation therapy and determining patient preference regarding treatment duration. When bleeding risk outweighs VTE recurrence risk or if the informed patient's preference is to stop treatment, anticoagulation should be stopped.[6] In some circumstances, elimination of the obstructing thrombus is warranted and the use of venous thrombectomy or thrombolysis can be considered.[6] Inferior vena cava interruption with a filter is also an option in those with contraindications to anticoagulation therapy or in whom anticoagulant therapy has failed.[6]

Once the diagnosis of VTE has been objectively confirmed (see Clinical Presentation and Diagnosis below), anticoagulant therapy with UFH, LMWH, or fondaparinux should be instituted as soon as possible. Evidence indicates that currently available injectable anticoagulants can be administered in the outpatient setting in most patients with DVT and some patients with PE. The decision to initiate therapy on an outpatient basis should be based on institutional resources and patient specific variables (Table 26–21).[75] 7

CLINICAL CONTROVERSY

For the treatment of an acute VTE, LMWHs should be dosed based on the patient's actual (or total) body weight. Some clinicians believe that dose adjustments or dosing "caps" are not recommended in obese patients. However, some clinicians continue to "cap" LMWH doses for patients weighing more than 150 kg.

UNFRACTIONATED HEPARIN

The parenteral administration of UFH followed by warfarin has been the conventional treatment of patients with VTE for decades and is still preferred in patients with severe renal insufficiency.[6] For acute treatment of VTE, UFH has traditionally be administered by continuous IV infusion (see Table 26–7). When UFH is administered by IV infusion, the aPTT or a suitable coagulation study is generally used to monitor the anticoagulant effect. The infusion rate should be adjusted to maintain an appropriate range corresponding to a heparin concentration of 0.3 to 0.7 international units/mL anti-Xa activity by the amidolytic assay.[6] Weight-based dosing of UFH achieves a therapeutic aPTT in the vast majority of patients in the first 24 hours (see Table 26–7).[5] Failure to give a sufficient dose of IV UFH has been shown to increase the risk of VTE recurrence not only during the initial treatment but also during long-term therapy.[6] Intravenous UFH requires hospitalization with frequent monitoring and dose adjustment. Well-organized inpatient anticoagulation management services have been shown to improve patient care by increasing the proportion of aPTT values in the therapeutic range, reducing the length of hospital stay, and lowering total hospital costs when compared with usual care.[76] However, despite the widespread use of weight-based dosing protocols, some patients still fail to achieve an adequate response to UFH therapy. There is also evidence that UFH does not prevent thrombus progression in some patients with DVT, and rebound thrombin generation has been observed when UFH is discontinued abruptly.[30] These limitations of traditional IV UFH in the acute treatment of VTE have led to the investigation of alternative approaches.

Evidence suggests that if a sufficient dose of UFH is administered, aPTT-guided dose titration may not be necessary. Weight-based LMWH compared to weight-based UFH (initial dose 333 units/kg subcutaneously followed by 250 units/kg twice daily) without coagulation monitoring for the treatment of acute VTE revealed no difference in recurrent VTE, major bleeding or death during follow-up. Both groups received warfarin therapy overlapped for at least 5 days and continued after LMWH or UFH was discontinued.[29] UFH administered in this manner may be a less costly option for treatment of acute VTE in appropriately selected patients. For patients weighing more than 80 kg, injection volume may be problematic since 20,000 unit/mL is the most concentrated commercially available preparation of UFH.

LOW-MOLECULAR-WEIGHT HEPARIN

Because of their improved pharmacokinetic and pharmacodynamic profile as well as ease of use, the LMWHs have largely replaced UFH for the treatment of VTE. The LMWHs given subcutaneously in fixed, weight-based doses (see Table 26–10) are at least as effective as UFH given IV for the treatment of VTE.[6] There appears to be similar efficacy and safety with inpatient or outpatient LMWH administration, once- or twice-daily dosing regimens, and use of different LMWH preparations.[6] However, a subgroup analysis in one study suggested that patients with cancer and obese patients have higher VTE recurrence rates with once-daily enoxaparin.[77]

TABLE 26-20 Consensus Guidelines for Venous Thromboembolism Treatment

	Recommendation	Grade[a]
Acute anticoagulation	Acute treatment of objectively confirmed DVT or PE should be with subcutaneous LMWH, subcutaneous fondaparinux, subcutaneous fixed-dose UFH, intravenous UFH, or adjusted-dose subcutaneous UFH	1A
	The dose of monitored UFH (subcutaneous or intravenous) should be sufficient to prolong the aPTT to a range that corresponds to a plasma heparin level of 0.3 to 0.7 international units/mL anti-Xa activity	1C
	LMWH (as an outpatient if possible) is recommended rather than intravenous UFH for patients with acute DVT	1C (outpatient); 1A (inpatient)
	UFH is suggested over LMWH for patients with severe renal failure	2C
Duration of acute treatment	Treatment with UFH, LMWH, or fondaparinux should be overlapped with warfarin for at least 5 d and until the INR is ≥2.0 for 24 h	1C
	Warfarin should initiated together with UFH, LMWH, or fondaparinux on the first treatment day	1A
	Patients with cancer should be treated with a LMWH for the first 3 to 6 mo	1A
Long-term anticoagulation	Warfarin (target INR 2.5, range: 2.0 to 3.0) should be continued for at least 3 mo *in all patients*	1A
	All patients with unprovoked VTE should be evaluated for the risk-benefit ratio of long-term anticoagulation	1C
	Patients with a first unprovoked proximal DVT or PE who are at low risk for bleeding and for whom good anticoagulant monitoring is achievable should receive long-term anticoagulation	1A
	Patients with recurrent unprovoked VTE should receive long-term anticoagulation	1A
	Patients receiving long-term anticoagulation should receive periodic reassessment of the risk-benefit ratio of continuing anticoagulation	1C
	In patients with cancer, following 3 to 6 mo of LMWH, subsequent anticoagulation with either warfarin or LMWH should continue indefinitely or until the cancer is resolved	1C

[a] Refers to grade of recommendation (1A, strong recommendation applying to most patients in most circumstances; 1C, strong recommendation applying to most patients in many circumstances; higher quality research likely to impact confidence in the estimate of effect and may well change the estimate; 2B, weak recommendation where alternative approaches likely to be better for some patients under some circumstances).

aPTT, activated partial thromboplastin time; DVT, deep vein thrombosis; INR, international normalized ratio; LMWH, low-molecular-weight heparin; PE, pulmonary embolism; UFH, unfractionated heparin; VTE, venous thromboembolism.

From Kearon et al.[6]

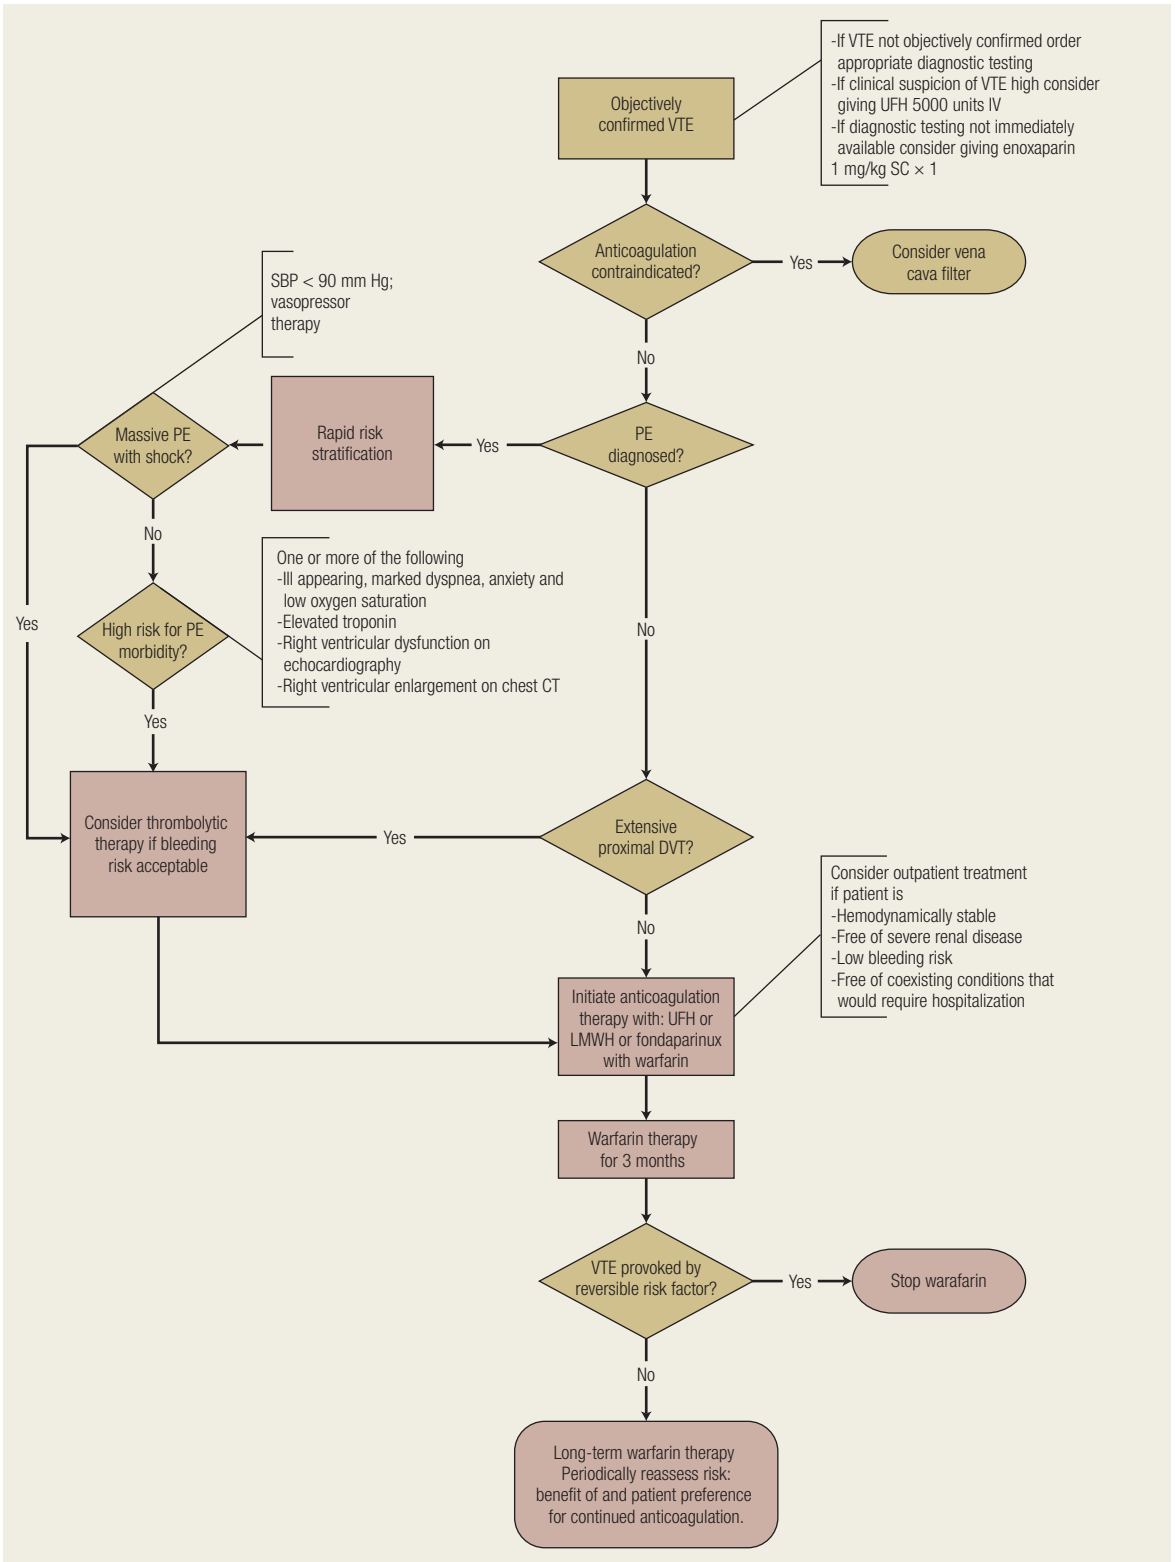

FIGURE 26-10. Treatment of venous thromboembolism (VTE). (IV, intravenous; SC, subcutaneous; DVT, deep vein thrombosis; LMWH, low-molecular-weight heparin; PE, pulmonary embolism; SBP, systolic blood pressure; UFH, unfractionated heparin.)

Given the predictable response and the reduced need for laboratory monitoring with LMWH, stable patients with DVT who have normal vital signs, low bleeding risk and no other comorbid conditions requiring hospitalization can be discharged early or treated entirely on an outpatient basis (see Table 26–21).[75] The efficacy and safety of LMWH in the home-based treatment of proximal DVT was initially established in large clinical studies. The results of randomized controlled clinical trials, as well as the experience of several successful outpatient DVT treatment programs in a variety of healthcare settings, have led to an increased acceptance for outpatient management. Indeed, surveys of patients who received outpatient DVT treatment indicate a high degree of satisfaction and comfort, with 91% expressing satisfaction with home treatment.[75]

TABLE 26-21 Outpatient Treatment Protocol for Deep Venous Thrombosis

Target population: Inclusion/exclusion criteria for outpatient venous thromboembolism (VTE) treatment
- Inclusion: Patients with objectively diagnosed VTE
- Relative exclusion: Patients with clinical evidence of pulmonary embolus or suspected embolism who are hemodynamically stable
- Exclusion: Arterial thromboembolism or patients who are currently receiving dialysis, actively bleeding, have had recent (within 2 weeks) major surgery/trauma, or have other severe uncompensated comorbid conditions

Recommended procedure: May vary depending on the patient's clinical condition

A. Confirm diagnosis of VTE by objective testing
1. Venous ultrasonogram
2. Ventilation–perfusion (V/Q) scan
3. Computed tomography (CT) scan

B. Day 1
1. Baseline laboratory evaluation
   a. Prothrombin time (PT) and calculated international normalized ration (INR)
   b. Activated partial thromboplastin time (aPTT)
   c. Serum creatinine (Scr)
   d. Complete blood count (CBC) with platelets
2. Medication
   a. Low-molecular-weight heparin (LMWH) or fondaparinux injections
      i. Enoxaparin 1 mg/kg subcutaneously (SC) q 12 h or
      ii. Enoxaparin 1.5 mg/kg SC q 24 h (not recommended for patients with cancer or for obese patients)
      iii. Dalteparin 100 units/kg SC q 12 h or
      iv. Dalteparin 200 units/kg SC q 24 h or
      v. Tinzaparin 175 units/kg SC q 24 h or
      vi. Fondaparinux 7.5 mg SC q 24 h (5 mg if <50 kg and 10 mg if >100 kg)
   b. Warfarin sodium 5–10 mg orally every evening
   c. Pain medication if necessary (avoid nonsteroidal antiinflammatory drugs [NSAIDs])
3. Patient education
   a. Clinical pharmacy/nursing
      i. Educate patient regarding the importance of proper monitoring of anticoagulation therapy and indications for additional medical evaluation; document activities in the medical record
      ii. Teach patient how to self-administer LMWH (if patient or family member unwilling or unable to self-administer LMWH injection, visiting nurse services should be arranged); initial LMWH injection should be administered in the medical office or hospital
      iii. Instruct patient regarding local therapy: elevation of affected extremity; localized heat, antiembolic exercises (flexion–extension of ankle for lower-extremity VTE, or hand squeezing–relaxation for upper-extremity VTE)
   b. Pharmacy operations
      i. Provide backup for clinical pharmacy/nursing; reinforce patient education regarding indication, use, monitoring, side effects, and drug interactions with antithrombotic therapy
      ii. Repackage LMWH syringes (if indicated) in patient-specific doses and dispense 5 to 7 days of therapy
      iii. Screen patient's pharmacy profile for potential drug–drug interactions with anticoagulation therapy
   c. Anticoagulation service enrollment
      i. The physician should forward outpatient VTE treatment orders to the anticoagulation service

C. Day 2
1. Laboratory evaluation: not required on day 2 of therapy
2. Medications: continue LMWH and warfarin as directed
3. Anticoagulation service
   a. Contact patient and evaluate for symptoms of pulmonary embolism (PE), clot extension, and/or bleeding
   b. Arrange for visiting nursing service if family or family member is having difficulty with outpatient therapy
   c. Continue reduced activity as long as pain persists (when possible, elevate extremity); increase activity as tolerated
   d. Document activities in medical record

D. Day 3
1. Laboratory evaluation: check INR
2. Medications: continue LMWH and warfarin directed
3. Anticoagulation service
   a. Contact patient and evaluate for symptoms of PE, clot extension, and/or bleeding
   b. Interpret results of INR and adjust dose of warfarin to achieve a target INR of 2.5
   c. Patient activity: continue reduced activity as long as pain persists (when possible, elevate extremity); increase activity as tolerated
   d. Document activities in medical record

E. Day 4
1. Laboratory evaluation: check INR
2. Medications: continue LMWH and warfarin as directed
3. Anticoagulation service
   a. Contact patient and evaluate for symptoms of PE, clot extensions, and/or bleeding
   b. Interpret results of INR and adjust dose of warfarin to achieve a target INR of 2.5
   c. Patient activity: no restrictions; if pain increases, contact anticoagulation service or provider
   d. Document activities in medical record

(continued)

TABLE 26-21 Outpatient Treatment Protocol for Deep Venous Thrombosis (continued)

F. Day 5
1. Laboratory evaluation: check INR and CBC with platelets
2. Medications: continue LMWH if indicated and warfarin as directed
3. Anticoagulation service
   a. Contact patient and evaluate for symptoms of PE, clot extension, and/or bleeding
   b. Interpret results of INR and adjust does of warfarin to achieve a target INR of 2.5
   c. Patient activity: no restriction; if pain increases, contact primary care provider
   d. Document activities in medical record

Patients presenting with PE and no evidence of hemodynamic instability are at low risk of subsequent morbidity and mortality. Evidence exists suggesting that patients with submassive PE who are hemodynamically stable can be managed safely as outpatients with LMWH or fondaparinux.[30] However, hemodynamically unstable patients with PE should generally be admitted for initiation of anticoagulation therapy. If thrombolytic therapy or embolectomy is anticipated, UFH, which can be rapidly reversed, is preferred.[78]

Not all patients are appropriate candidates for outpatient DVT treatment. At a minimum, patients with objectively diagnosed DVT must be reliable or have adequate caregiver support.[75] Patients and their caregivers must be willing and active participants in the outpatient management of DVT (Table 26–22). Patients who are unable to manage or who decline at-home treatment should be admitted to the hospital. These patients may subsequently opt for early discharge on LMWH. Daily patient contact either in person or via telephone is essential to identify potential complications and to address questions and concerns promptly. During daily contacts patients must be asked about symptoms that may indicate bleeding, thrombus extension, and PE.[75] Once acute treatment with LMWH has been transitioned to long-term warfarin therapy (usually after about 5 to 10 days), patient contact can occur less frequently.

FONDAPARINUX

Fondaparinux has been shown to be a safe and effective alternative to LMWH for the treatment of VTE.[6] Fondaparinux is dosed once daily via subcutaneous injection based on weight in the following doses: 5 mg if <50 kg, 7.5 mg if 50 kg to 100 kg, and 10 mg if >100 kg.[37] Careful attention should be paid to renal function when fondaparinux is used to treat VTE.

WARFARIN

Warfarin monotherapy is an unacceptable choice for the acute treatment of VTE because it does not produce a rapid anticoagulation effect and is associated high incidence of recurrent thromboembolism. However, warfarin is very effective in the long-term management of VTE and should be started concurrently with rapid acting injectable anticoagulant therapy.[6] The rapid-acting injectable anticoagulant should overlap with warfarin therapy for at least 5 days and until INR ≥2.0 has been achieved for at least 24 hours.[6] The initial dose of warfarin should be 5 to 10 mg (see Fig. 26–8) and periodically adjusted to achieve and maintain an INR between 2.0 and 3.0.

The appropriate initial duration of warfarin therapy to effectively treat an acute first episode of VTE for all patients is 3 months. The one exception to this rule is that isolated distal DVT provoked by a major transient risk factor can safely be treated with only 6 weeks of warfarin therapy.[6] Three months of warfarin therapy reduces the risk of recurrent VTE to as low a value as can be achieved by a time-limited duration of therapy. To prevent new episodes of VTE that are not directly related to the preceding episode, continued warfarin therapy is required.[79] Individually tailoring warfarin maintenance duration therapy for 3 months requires careful consideration of the circumstances surrounding the initial thromboembolic event, the presence of ongoing thromboembolic risk factors, and the risk of bleeding and patient preference.[6] The most important consideration in determining the risk of recurrent VTE once anticoagulation therapy is stopped is whether the initial thrombotic event was associated with a major transient or reversible risk factor (e.g., surgery, plaster cast immobilization of a leg, or hospitalization in the month prior to VTE). For patients in this situation, the risk of recurrence is relatively small, approximately 3% in the first year and approximately 10% over 5 years, and only 3 months of oral anticoagulation treatment is warranted.[79] For VTE associated with a minor transient or reversible risk factor (e.g., within 6 weeks of initiation of estrogen therapy, air travel lasting >8 hours, pregnancy, less marked leg injuries or immobilization, or the aforementioned major risk factors when they have occurred 1 to 3 months prior to VTE), 3 months of oral anticoagulation therapy is also reasonable.[79]

Patients with a first unprovoked (idiopathic) VTE have a recurrence risk of approximately 10% in the first year and approximately 30% and 50% over 5 and 10 years, respectively. These patients should be considered for indefinite warfarin therapy when feasible.[6] Indefinite in this context refers to warfarin that is continued without a scheduled stop date, but which may be stopped because of a subsequent increase in the risk of bleeding or change in patient preference for anticoagulation.[6] Indefinite warfarin therapy targeted to an INR of 2.0 to 3.0 reduces recurrent VTE by about 90% with the trade off of a doubled frequency of major bleeding rate to about 1% to 2% per year.[79] Factors that may lead to the decision to stop warfarin therapy after 3 months include noncompliance with warfarin therapy, initial clot although idiopathic was isolated in calf veins, or a moderate to high risk of bleeding.[6] Clinically important risk factors for bleeding include age >75 years, previous non-cardioembolic stroke, history of gastrointestinal bleeding, renal or hepatic impairment, anemia, thrombocytopenia, concurrent antiplatelet use (avoid if possible), noncompliance, poor anticoagulant control, serious acute or chronic illness, and the presence of a structural lesion (e.g., tumor, recent surgery) expected to be associated with bleeding. Presence of one to two bleeding risk factors suggests moderate bleeding risk while three or more risk factors suggest a high bleeding risk.[79] For patients with second episode of idiopathic VTE, indefinite anticoagulation is recommended.[6]

Various strategies aimed at identifying patients at very low risk of recurrence after a first idiopathic VTE are being evaluated in clinical trials. Safe withdrawal of warfarin therapy may be possible if reliable identification of these patients proves possible. Estimating an individual patient's risk of recurrent VTE using a variety of interacting clinical, laboratory, and radiologic findings can be accomplished with increasing precision.[80] Some factors that may predict lower risk of recurrence include female gender, low D-dimer levels 1 month after stopping warfarin therapy, absence of residual clot on ultrasound, absence of hereditary and acquired thrombophilia, and absence of the postthrombotic syndrome.[79]

TABLE 26-22 Patient Education for Outpatient Deep Vein Thrombosis Therapy

General information regarding DVT and the goals of treatment
- Anticoagulant medications (injections and warfarin tablets) have been prescribed to prevent the blood clot from growing larger so that the body can begin to dissolve the clot
- Your body may be able to completely dissolve the clot, but in some cases the clot never goes completely away; even with adequate anticoagulation therapy, some people will have chronic pain and swelling in the affected extremity; people who have had one clot are at increased risk of having future clots
- Warfarin tablets take several days to begin to work; LMWH injections work right away so at first LMWH injections and warfarin tablets are used together
- When the warfarin has become effective, you will be able to stop the LMWH injections; you will continue to take warfarin tablets for 3 to 6 months or longer to prevent blood clots from returning
- It is important for you to administer your LMWH or fondaparinux and warfarin exactly as directed

Subcutaneous injection technique
- You must learn to give yourself a subcutaneous injection of LMWH or fondaparinux; alternatively, you may have a family member or visiting nurse give it to you
- If your LMWH or fondaparinux syringes were filled by the manufacturer, they can be stored at room temperature; if your syringes were filled by the pharmacy, they should be stored in the refrigerator; if you were instructed to fill your own syringes, you should prepare the syringe immediately prior to injecting its contents
- If you see a bubble in the syringe, do not try to get it out, you may accidentally squirt out part of your dose
- Choose an injection site on your abdomen; clean the area with alcohol, then position an uncapped syringe at a 90-degree angle; pinch the skin, stick the needle in as far as it will go and gently but firmly push the plunger down; this will inject the medicine into the skin; when all the medication has been injected, remove the needle and dispose of it in an appropriate container
- You will likely experience a burning sensation when the medication is injected; this will go away after a few minutes
- Rotate injection sites from side to side, do not inject into the same site more than once; avoid the area around your navel; do not inject into any bruises

Blood test monitoring
- Regular blood tests are required to make sure your medication is working properly
- The prothrombin time tells how quickly your blood forms a clot; it is used to tell how well warfarin is working
- The INR is a way to standardize the prothrombin time between laboratories; your goal INR range is between 2.0–3.0; if your INR is <2.0, you are at higher risk for clotting, if your INR is >3.0, you are at higher risk for bleeding; your dose of warfarin will be adjusted based on the results of this test
- You need to have a complete blood count test both before you begin therapy and after you have been on LMWH or fondaparinux for about 5 days; this will help detect internal bleeding and the occurrence of a rare side effect of heparin therapy that can decrease a component of your blood called platelets

Warfarin information
- Each strength of warfarin has a unique color; each time you refill your prescription, make sure your new tablets are the same color you have been taking; if they are not the same color, ask your pharmacist why
- Warfarin should be taken at approximately the same time each day
- The most common and serious side effect of warfarin is bleeding; you should be careful to avoid situations or activities that increase your risk of injury; apply direct pressure to control bleeding from superficial cuts
- Warfarin has many drug interactions; always check with your provider before taking any new medications (including over-the-counter medications and dietary supplements)
- Foods rich in vitamin K (green leafy vegetables, etc.) may interfere with warfarin; you do not need to avoid foods rich in vitamin K, but you should try to maintain consistent dietary habits
- Alcohol can increase your risk for bleeding and interfere with warfarin therapy; drink alcohol in moderation (1–2 drinks per day); avoid binge drinking

Contact your provider if you experience
- Persistent bleeding from a cut or scrape
- Blood in your urine
- Blood in your stool
- Persistent nose bleeding
- Increased swelling or pain in your affected extremity

Go to the emergency department if you experience
- Shortness of breath
- Chest pain
- Coughing up blood
- Black tarry-appearing stool
- Severe headache of sudden onset
- Slurred speech

DVT, deep vein thrombosis; INR, international normalized ratio; LMWH, low-molecular-weight heparin.

Risk assessment tools derived from combining several independent risk factors for recurrence has also been investigated.[81] While low D-dimer level one month after stopping warfarin therapy currently appears to hold the greatest promise as a method for identifying patients who could possibly stop warfarin therapy due to low risk of recurrence, further validation is needed before any one factor or prediction rule using a combination of factors can justify routinely stopping warfarin after 3 months of therapy.[79] The decision to continue anticoagulation therapy indefinitely should be reassessed periodically.[6] Patients should be involved in any decision to continue anticoagulation therapy with consideration given to the patient's long-term prognosis, risk of bleeding, ability to adhere to anticoagulation therapy instructions, financial resources, lifestyle, and quality of life.[6]

Increasingly, patients with VTE are being tested for hereditary and acquired hypercoagulable states (thrombophilia). The available evidence does not support an association between genetically transmitted thrombophilias and a higher chance of recurrent VTE.[11] Despite a lack of convincing evidence, most experts recommend indefinite anticoagulation for individuals with the antiphospholipid antibody syndrome, homozygotes for the factor V Leiden mutation, and heterozygotes with both the factor V Leiden and prothrombin 20210 gene mutations.

THROMBOLYSIS AND THROMBECTOMY

Most cases of VTE require only anticoagulation therapy. In rare cases, however, removal of the occluding thrombus by either

pharmacologic or surgical means may be warranted.[6] Consensus panel recommendations regarding either thrombolysis or thrombectomy in the management of VTE are based on low-quality evidence, and more study is clearly needed to clarify their precise role.

Thrombolytic agents are proteolytic enzymes that enhance the conversion of plasminogen to plasmin which subsequently degrades the fibrin matrix. Thrombolytic therapy for DVT should theoretically improve long-term outcomes and reduce the risk of recurrent VTE. Indeed, thrombolytic therapy improves venous patency.[6] There is some evidence from pooled study analyses suggesting that thrombolytic therapy is superior to anticoagulation therapy alone in preventing postthrombotic morbidity.[6] Catheter-directed instillation of a thrombolytic agent directly into the clot is increasingly being used. The risk of bleeding associated with catheter-directed drug administration appears to be less than systemic administration.[6] Patients who present within 14 days of symptom onset with extensive proximal DVT, with good functional status, low bleeding risk and a life expectancy of a year or more are candidates for thrombolysis (Table 26–23). Catheter-directed thrombolysis is preferred provided appropriate expertise and resources are available. Catheter-based fragmentation of thrombus, with or without aspiration of the thrombus fragments, can be combined with catheter-directed thrombolysis and the combination has been associated with shorter treatment times and reduced cost.[6] The same duration and intensity of anticoagulation therapy is recommended as for DVT patients who do not receive thrombolysis.[6]

In the management of acute PE, successful dissolution of fibrin with thrombolytic therapy reduces elevated pulmonary artery pressure and normalizes right ventricular dysfunction. However, the risk of death from PE should outweigh the risk of serious bleeding associated with thrombolytic therapy. Patients being considered for thrombolytic therapy should be screened carefully for contraindications relating to bleeding risk (e.g., intracranial disease, uncontrolled hypertension at presentation, and recent major surgery or trauma).[6]

Thrombolytic therapy is considered the standard of care for patients with massive PE manifested by shock and cardiovascular collapse (about 5% of patients diagnosed with PE).[6] These patients have the highest risk of mortality and require aggressive interventions such as volume expansion, vasopressor therapy, intubation, and mechanical ventilation in addition to antithrombotic therapy.[78] Thrombolytic therapy in these patients should be administered without delay to reduce the risk of progression to multisystem organ failure and death. While life-saving in the acute phase of massive PE with hypotension, the hemodynamic benefit of thrombolysis is comparable to that of heparin after a few days.[80]

The benefit of thrombolytic therapy in patients with severe PE without hemodynamic compromise is less clear and rapid risk stratification is required to determine whether the patient will benefit from thrombolysis or embolectomy in addition to anticoagulation therapy.[78] Risk stratification helps inform the intensity of initial treatment, low risk patients being discharged early or managed as outpatients and high risk patients receiving intensive surveillance in the intensive care unit and/or advanced therapies such as thrombolysis.[82] Three key components of risk stratification are clinical evaluation, determination of cardiac biomarker levels such as troponin, and assessment of right ventricular size and function.[6,78] The Pulmonary Embolism Severity Index (PESI) is a prognostic tool utilizing 11 routinely available clinical parameters namely demographics (age and gender), comorbid illnesses (cancer, heart failure, and chronic lung disease) and clinical findings (pulse, systolic blood pressure, respiratory rate, temperature, mental status, and arterial oxygen saturation) that accurately stratifies patients into five risk classes with classes I and II considered low risk.[82] Poor prognostic indicators include patients who appear ill, with marked dyspnea, anxiety, and low oxygen saturation; elevated troponin levels; right ventricular dysfunction on echocardiography; and right ventricular enlargement on chest CT. Patients with one or more of these clinical features are at high risk for PE-related morbidity and mortality and may benefit from thrombolytic therapy, provided bleeding risk is acceptable, even in the absence of hemodynamic compromise (see Table 26–23).[6] The optimal role of thrombolysis in the management of PE requires further study and it is important to note that current data has not shown a benefit of thrombolytic therapy in submassive PE despite recruitment of over 800 patients in several studies.[80,82]

In high-risk patients, whose clinical status may rapidly deteriorate necessitating the need for thrombolysis or thrombectomy, initial anticoagulation with short-acting intravenous UFH may be preferred.[78] The most common thrombolytic agent for PE is alteplase at a dose of 100 mg via a peripheral vein over 2 hours with or without concomitant intravenous UFH (suspending UFH during alteplase administration is the more common practice in the United States).[6]

Actual removal of clot can be achieved by catheter-directed interventions or surgery and is usually reserved for the patient who is either not a candidate for or has not responded to thrombolysis.[6,78] For DVT, catheter-based interventions are not recommended unless combined with catheter-directed thrombolysis.[6] In rare circumstances surgical thrombectomy for extensive ileofemoral DVT may be necessary, but catheter-directed

TABLE 26-23 Thrombolysis for the Treatment of Venous Thromboembolism

- The majority of patients with VTE do not require thrombolytic therapy
- Thrombolytic therapy for DVT should be reserved for patients who present with extensive proximal DVT (e.g., ileofemoral) within 14 days of symptom onset, have good functional status, and are at low risk of bleeding
- Thrombolytic therapy should be administered to patients with massive PE with evidence of hemodynamic compromise (hypotension or shock) unless contraindicated by bleeding risk
- Thrombolytic therapy should be considered for selected high-risk patients without hypotension provided the risk of bleeding is acceptable
- Factors associated with high risk for adverse PE outcomes include
  - Ill-appearing patients with marked dyspnea, anxiety, and low oxygen saturation
  - Elevated troponin levels
  - Right ventricular dysfunction on echocardiography
  - Right ventricular enlargement on chest CT
- Factors that increase the risk of bleeding must be evaluated before thrombolytic therapy is initiated (i.e., recent surgery, trauma or internal bleeding, uncontrolled hypertension, recent stroke or intracranial hemorrhage)
- Baseline labs should include CBC and blood typing in case transfusion is needed
- Alteplase 100 mg infused via peripheral vein over 2 hours is the most commonly used thrombolytic for patients with PE
- Before thrombolytic therapy for PE, intravenous UFH should be administered in full therapeutic doses
- During thrombolytic thereapy it is acceptable to either continue or suspend intravenous UFH (suspending UFH is the most common practice in the U.S.)
- aPTT should be measured following the completion of thrombolytic therapy
  - If aPTT is <80 seconds, UFH infusion should be started and adjusted to maintain aPTT in therapeutic range
  - If aPTT is >80 seconds, remeasure every 2–4 hours and start UFH infusion when aPTT is <80 seconds
- Avoid phlebotomy, arterial puncture, and other invasive procedures during thrombolytic therapy to minimize the risk of bleeding

aPTT, activated partial thromboplastin time; CBC, complete blood cell count; DVT, deep vein thrombosis; PE, pulmonary embolism; UFH, unfractionated heparin.
From Kearon et al.[6] and Goldhaber.[78]

thrombolysis is preferred if bleeding risk is acceptable.[6] For treatment of acute PE, catheter-based embolectomy might be particularly suitable for patients too frail for surgery (surgical pulmonary embolectomy requires cardiopulmonary bypass).[78] Catheter-based embolectomy in PE can be combined with catheter-directed thrombolysis although catheter embolectomy is usually attempted first with combined therapy reserved for those not responding to mechanical intervention alone.[78] Surgical embolectomy is effective for massive PE and hemodynamic instability when thrombolysis is contraindicated and for when thrombolysis has failed clinically.[78] In cases of chronic PE—where persistent emboli produce CTPH, hypoxemia, and right-sided heart failure—surgical pulmonary thromboendarterectomy offers greater benefit than anticoagulants and may be the treatment of choice if performed by an experienced surgical team. A permanent vena cava filter is usually inserted before or during the procedure and these patients need indefinite oral anticoagulation therapy targeted to an INR of 2.5 (range, 2.0–3.0).[6]

VENA CAVA INTERRUPTION

Anticoagulation therapy is the accepted standard for treating DVT and PE. However, an IVC filter may be indicated in special situations when anticoagulants are ineffective or unsafe, including in (a) patients with an absolute contraindication to anticoagulation therapy because of active bleeding or anticipated bleeding from a predisposing lesion; (b) patients with a massive PE who survive but in whom recurrent embolism might be fatal; (c) patients who have recurrent VTE despite adequate anticoagulation therapy; and (d) demonstration of large free-floating clot loosely attached to the wall of the IVC.[67] There is little evidence to support the widespread use of vena cava filters. Vena cava filters reduce the risk of PE in the short-term, but also appear to increase the long-term risk for recurrent DVT presumably as a consequence of the accumulation of thrombus on the filter, which may partially occlude the vena cava, resulting in venous stasis.[67] Patients with permanent IVC filters should probably receive anticoagulant therapy as soon as possible and continue it indefinitely.[67] Given these concerns, retrievable filters that can be removed after the period of greatest risk for PE or after a transient bleeding risk has resolved have been developed and have been suggested for use in patients with transient contraindications to anticoagulation therapy. In reality most (65% in one report) "retrievable" filters are not removed.[67]

ANCILLARY THERAPY

In addition to anticoagulant therapy for patients with proximal DVT, wearing graduated compression stockings can reduce the risk of developing the postthrombotic syndrome by 50%.[80] To be effective, graduated compression stockings must fit properly and provide adequate pressure at the ankle (30–40 mm Hg). While the use of elastic compression stockings should be recommended for all patients with symptomatic DVT, in reality the discomfort associated with wearing properly fitted stockings along with the expense and unflattering cosmetic appeal makes routine use of compression stockings undesirable for many patients.

Strict bedrest was traditionally recommended following acute DVT based on the assumption that leg movement would dislodge the clot, resulting in PE. However, the evidence contradicts this assumption. Ambulation in conjunction with graduated compression stockings results in faster reduction in pain and swelling with no apparent increase in the rate of clot embolization.[6] Early ambulation and continued high activity level also reduce the likelihood of postthrombotic syndrome.[80] Patients should be encouraged to ambulate as much as their symptoms permit. If pain and swelling increase with ambulation, the patient should be instructed to lie down and elevate the affected leg until symptoms subside.

TREATMENT OF VENOUS THROMBOEMBOLISM IN SPECIAL POPULATIONS

Certain patient populations require unique considerations as outlined in the following sections.

Pregnancy

The use of anticoagulation therapy for the treatment of DVT or PE in pregnant women is common.[16] UFH and LMWH are the preferred anticoagulants for use during pregnancy (Table 26–24). They do not cross the placenta and evidence suggests they are safe for the fetus.[16] Warfarin should be avoided because it crosses the placenta and can produce fetal bleeding, central nervous system abnormalities, and embryopathy. The direct thrombin inhibitors also cross the placenta. To date, fondaparinux has not been formally evaluated in pregnant patients.[5]

Long-term UFH therapy has been linked to significant bone loss and osteoporosis, requires multiple daily injections, and must be monitored frequently (every 1–2 weeks) throughout pregnancy. Because of these limitations, many experts suggest the use of LMWH over UFH throughout pregnancy.[16] The evidence supporting this preference is weak however and UFH has been successfully used to prevent and treat VTE during pregnancy.[32] Anticoagulation for acute DVT during pregnancy should continue for at least 6 months postpartum (minimum total duration of therapy of 6 months).[16]

Pediatric Patients

Although seen far more frequently in adults, VTE in pediatric patients has become increasingly common secondary to prematurity, cancer, trauma, surgery, congenital heart disease, and systemic lupus erythematosus. Pediatric patients often develop DVTs associated with an indwelling central venous catheter. In contrast to adults, pediatric patients rarely develop idiopathic VTE.[33] While recommendations for antithrombotic therapy in pediatric patients are largely extrapolated from recommendations in adults, there are likely important pharmacokinetic and pharmacodynamic differences when antithrombotic medications are given to pediatric patients. The majority of literature supporting pediatric recommendations is derived from uncontrolled studies, case reports, or in vitro experiments. When possible, a pediatric hematologist with experience managing VTE should manage pediatric patients.[33]

Anticoagulation with UFH and warfarin remains the most frequently used approach for the treatment of VTE in pediatric patients. The recommended target aPTT and INR ranges as well as the duration of therapy are extrapolated from clinical trials in adults. Recent data suggest that extrapolating aPTT range from adults to pediatric patients is unlikely to be valid. However, in the absence of supporting clinical data, extrapolation of the adult aPTT range to pediatric patients remains necessary.[33] The recommended initial bolus dose of UFH is 75 to 100 units/kg given intravenously over 10 minutes followed by a maintenance infusion of 28 units/kg/h for infants 2 to 12 months of age and 20 unit/kg/h for children age 1 year or older.[33] Subsequent adjustments should be made every 4 to 6 hours to maintain the aPTT within the institution-specific therapeutic range. The usual warfarin starting dose is 0.2 mg/kg with a maximum of 10 mg. Infants require higher doses of warfarin per kg to maintain a target INR of 2.0 to 3.0 compared to teenagers and adults (mean dose 0.33 mg/

TABLE 26-24 Unfractionated and Low-Molecular-Weight Heparin Use During Pregnancy

Acute treatment	LMWH • Enoxaparin 1 mg/kg SC q 12 h or 1.5 mg/kg q 24 h *or* • Dalteparin 100 U/kg SC q 12 h *or* • Tinzaparin 175 U/kg SC q 24 h *or* UFH • Initiate using weight-based intravenous therapy and adjust dose to achieve therapeutic anti-Xa level for at least 5 days • Transition to SC adjusted-dose UFH administered q 8–12 h with midinterval anti-Xa activity in the therapeutic range[a]
Long-term treatment[b]	LMWH Maintain initial LMWH dose regimen throughout pregnancy *or* Alter LMWH dose in proportion to any weight change (usually gain) *or* Obtain monthly anti-Xa level measurements 4–6 hours after morning dose and adjust LMWH dose based on anti-Xa level (target = 0.5–1.2 units/mL if twice daily dosing; 1.0 to 2.0 units/mL if once-daily dosing) *or* UFH Obtain anti-Xa level at the midpoint of the dosing interval and adjust UFH dose to achieve an anti-Xa level of 0.3–0.7 units/mL
Issues at time of delivery	Elective induction of labor • Discontinue UFH or LMWH 24 hours prior to induction • Initiate therapeutic doses of UFH by IV infusion and discontinue 4–6 hours prior to expected time of delivery if risk of recurrent VTE is deemed high Spontaneous labor • For LMWH, if there is a reasonable expectation that significant anticoagulant effect will be present at time of delivery (a) epidural should be avoided, and (b) reversal with protamine sulfate may be considered • For UFH, monitor the aPTT and reverse with protamine sulfate if aPTT is prolonged near the time of delivery Postpartum • Commence UFH or LMWH as soon as safely possible (usually 12 hours following delivery) • Concurrently initiate warfarin therapy and discontinue UFH or LMWH when the INR is ≥2.0 • Continue anticoagulants for at least 4 weeks following delivery • Warfarin can be safely used by women who are breastfeeding

[a] Anti-Xa monitoring preferred as the relationship between aPTT and heparin levels differs in pregnant compared to nonpregnant patients.

[b] As pregnancy progresses the volume of distribution of LMWH changes, glomerular filtration rate increases, and most women gain weight.

aPTT, activated partial thromboplastin time; INR, international normalized ratio; IV, intravenous; LMWH, low-molecular-weight heparin; SC, subcutaneously; UFH, unfractionated heparin; VTE, venous thromboembolism.

From Bates et al.[16] and Ginsberg and Bates.[100]

kg, 0.09 mg/kg, and 0.04 to 0.08 mg/kg, respectively). The INR target range is 2.0 to 3.0. Frequent INR monitoring and warfarin dose adjustments are typically required. When compared to adults, only 10% to 20% of pediatric patients can be safely monitored once monthly. Obtaining coagulation monitoring tests in pediatric patients is problematic because many have poor or nonexistent venous access. To address this problem, many clinicians recommend using fingerstick blood samples with a portable point-of-care monitor.[33] Because LMWHs have low drug-interaction potential, are less likely to cause HIT or osteoporosis, and require less frequent laboratory testing, they are an attractive alternative in pediatric patients. Enoxaparin, dalteparin, tinzaparin, and reviparin have been evaluated in pediatric patients. Most experts recommend that anti-Xa activity be monitored and the dose adjusted to maintain antifactor Xa levels between 0.5 and 1.0 units/mL 4 to 6 hours following subcutaneous injection. Compared to adults, children younger than 2 to 3 months of age or who weigh less than 5 kg have higher per-kilogram dose requirements to achieve a "therapeutic" response. The doses of LMWH for older children are generally similar to the weight-adjusted doses used in adults.[33] Warfarin can be initiated concurrently with UFH or LMWH therapy. Therapy should be overlapped for a minimum of 5 days and until the INR is therapeutic. Warfarin should be continued for at least 3 months for provoked VTE and 6 months for idiopathic VTE.[33] Thrombolysis and thrombectomy have been successfully employed in pediatric patients but published data are very limited—routine use is not recommended.[33]

Patients with Cancer

VTE is a frequent complication of malignancy. Furthermore, compared to patients without cancer, the rate of recurrent VTE in patients with cancer is threefold higher.[14] Warfarin therapy in cancer patients is often complicated by drug interactions (e.g., chemotherapy and antibiotics) and the need to frequently interrupt therapy for invasive procedures (e.g., thoracentesis, percutaneous biopsies, and abdominal paracentesis). Maintaining stable INR control is more difficult in this patient population because of nausea, anorexia, and vomiting.

CLINICAL CONTROVERSY

Evidence suggests that LMWH administered for 3 to 6 months after a DVT or PE is more effective than warfarin in preventing recurrent VTE events in patients with cancer. Despite the fact that current consensus guidelines recommend the use of a LMWH over warfarin for the long-term treatment of VTE in cancer patients, many practitioners still prefer the use of warfarin in these patients.

Randomized trials provide evidence that long-term LMWH monotherapy for VTE in cancer patients significantly decrease the rate of recurrent VTE without increasing bleeding risks compared to traditional therapy with warfarin.[6] Despite compelling data that cancer patients should be given LMWH instead of warfarin for the long-term treatment of VTE, the economic implications of this strategy have not yet been evaluated. In the absence of insurance coverage to offset the relatively high cost of long-term LMWH therapy, most patients are unable to afford it. Meta-analysis of 6 randomized, controlled clinical trials demonstrated no survival advantage of LMWH monotherapy compared to traditional therapy with warfarin.[83]

For patients with VTE and cancer who do receive LMWH, therapy should continue for at least the first 3 to 6 months of long-term treatment, at which time further LMWH can be considered or warfarin therapy can be substituted.[6] Anticoagulation therapy should continue for as long as the cancer is "active" and while the patient is receiving antitumor therapy.[6] A risk-to-benefit assess-

ment should be performed on a regular basis and the overall clinical status of the patient should be considered, along with the risk for bleeding, quality of life, and life expectancy.[6] Many patients with terminal cancer receiving palliative care prefer LMWH over warfarin.[84] Consideration should be given to stopping anticoagulant therapy even in the presence of active cancer for patients who are at very high risk of bleeding complications.[85]

PHARMACOECONOMIC CONSIDERATIONS

Hospitalization is the main cost driver in the management of VTE.[86] Although the drug acquisition cost for the LMWHs and fondaparinux are substantially higher than UFH, avoiding hospitalization dramatically decreases the overall costs of DVT treatment. Cost-effectiveness analyses using decision modeling suggests that the treatment of DVT with LMWHs is more cost effective than the treatment with UFH in both inpatient and outpatient settings.[87] Based on this decision model, the LMWHs will reduce overall healthcare cost if as few as 8% of patients are treated entirely on an outpatients basis or 13% of patients are discharged from hospital early.

Despite the substantial cost savings stemming from outpatient DVT treatment from the perspective of the insurer, the reality is that some patients are unable to afford LMWH or fondaparinux prescriptions and are therefore denied outpatient treatment. Fixed dose UFH as described previously may provide a lower cost option for the outpatient treatment of VTE for selected patients who otherwise would not have been able to afford it.[29]

HEPARIN-INDUCED THROMBOCYTOPENIA

HIT is an uncommon but extremely serious adverse effect associated with heparin use.[31] The immune-mediated platelet activation and thrombin generation seen during HIT can lead to severe and unusual thrombotic complications. Morbidity and mortality associated with HIT is disturbingly high—up to 50% of patients who develop the disorder will suffer a thrombotic complication or die within 30 days in the absence of treatment. The diagnosis of HIT is based on laboratory findings that confirm heparin antibody formation and platelet activation (Table 26–25). To prevent the thrombotic complications associated with HIT, prompt discontinuation of heparin and initiation of an alternative anticoagulant therapy is imperative.[31]

ETIOLOGY AND PATHOPHYSIOLOGY OF HIT

Two types of thrombocytopenia associated with heparin use have been described.[88] As many as 25% of patients receiving heparin therapy develop a benign, mild reduction in platelet counts referred to as non–immune-mediated heparin-associated thrombocytopenia (HAT; previously called HIT type 1). HAT produces a transient fall in platelet count that occurs early, typically between days 2 and 4 of heparin therapy. The degree of thrombocytopenia is usually mild, with platelet counts rarely going below 100,000 mm^3. It is not necessary to discontinue heparin therapy in these patients as platelet counts generally rebound to baseline values despite continued use. The exact mechanism of HAT is unknown; however, it may be the result of platelet aggregation, a dilutional effect, or diminished platelet production often seen in acutely ill patients. No clinical sequelae are associated with this benign phenomenon.

The second type of thrombocytopenia associated with heparin use is known as immune-mediated HIT (formally known as HIT type 2).[44,88] HIT is a severe pathologic adverse effect of heparin with a significant potential to cause thrombotic complications (see Table 26–25). The time course and magnitude of thrombocytopenia associated with HIT differs from that of HAT. Platelet counts typically begin to fall 5 to 10 days following initiation of heparin and reach a nadir by days 7 to 14. The development of thrombocytopenia can be delayed (delayed-onset HIT) up to 20 days, and begin several days after heparin has been stopped in patients naive to heparin therapy. Conversely, so-called rapid-onset HIT can occur rapidly and abruptly (within 24 hours following heparin initiation) in patients with a recent exposure to heparin (i.e., previous 3 months).[31] Platelet counts commonly fall below 150,000 mm^3 but rarely nadir as low as 20,000 mm^3. In some cases, overt thrombocytopenia may not occur, but a drop in platelet count greater than 50% from baseline is considered indicative of HIT.[31]

TABLE 26-25 Presentation of Heparin-Induced Thrombocytopenia

General	Venous thromboembolism is the most common presentation of heparin-induced thrombocytopenia (HIT), although arterial events (e.g., myocardial infarction, stroke) can occur. HIT should be suspected if a patient develops a deep vein thrombosis or pulmonary embolism while or soon after receiving unfractionated heparin.
Symptoms and signs	Thromboembolic events secondary to HIT produce the same signs and symptoms as those of other etiologies (see Clinical Presentation and Diagnosis).
Laboratory tests	The patient's platelet- count will typically be below 150,000/mm^3 or drop more than 50% from baseline. The platelet count usually drops after 5 to 10 days of unfractionated heparin therapy, but may drop sooner if the patient has received heparin in the past 3 months.
Other diagnostic tests	An enzyme-linked immunoabsorbent assay (ELISA) for the presence of antibodies to the heparin–PF4 complex should be performed to confirm the diagnosis. Functional assays, including the heparin-induced platelet activation assay (HIPAA), the serotonin release assay (SRA), or the platelet-aggregation assay (PAA), may also be performed to confirm the diagnosis.

The frequency of immune-mediated HIT is most powerfully related to the duration and type of heparin used and to a lesser extent the dose and route of administration.[31,44] The incidence of HIT associated with intravenous full dose UFH given for prolonged periods is significantly higher than that of low-dose subcutaneous UFH or LMWHs. The estimated overall incidence of HIT after 5 days of UFH use is 1% to 3% but the cumulative incidence may be as high as 6% after 14 days of continuous intravenous use. The incidence of HIT with low dose subcutaneous UFH in medical patients has been reported to be approximately 1%.[89] Low-molecular-weight heparins are associated with a significantly lower risk of HIT (<1%).[31] The incidence of HIT is higher with bovine UFH versus porcine UFH. In addition, the HIT risk varies with the exposed patient population: surgical patients > medical patients > pregnant patients.[31]

The pathogenesis of HIT involves an immunoglobulin mediated response to the heparin molecule leading to platelet activation and thrombin generation (Fig. 26–11).[44,88] With platelet activation there is release of PF4 from platelet granules. Heparin binds to PF4 forming a negatively charged polysaccharide molecule that is highly antigenic and stimulates the production of immunoglobulin (Ig) G antibodies. Although heparin-induced antibody formation occurs in 10% to 20% of patients treated with heparin, the vast majority never develop HIT. In patients who develop HIT, the heparin–PF4–IgG complexes bind to the Fc receptor on platelets, leading to further platelet activation and the release of PF4 and procoagulant microparticles from platelet granules. In addition, PF4 and heparin-like molecules bind to the surface of endothelial cells resulting in antibody-induced endothelial cell damage and the

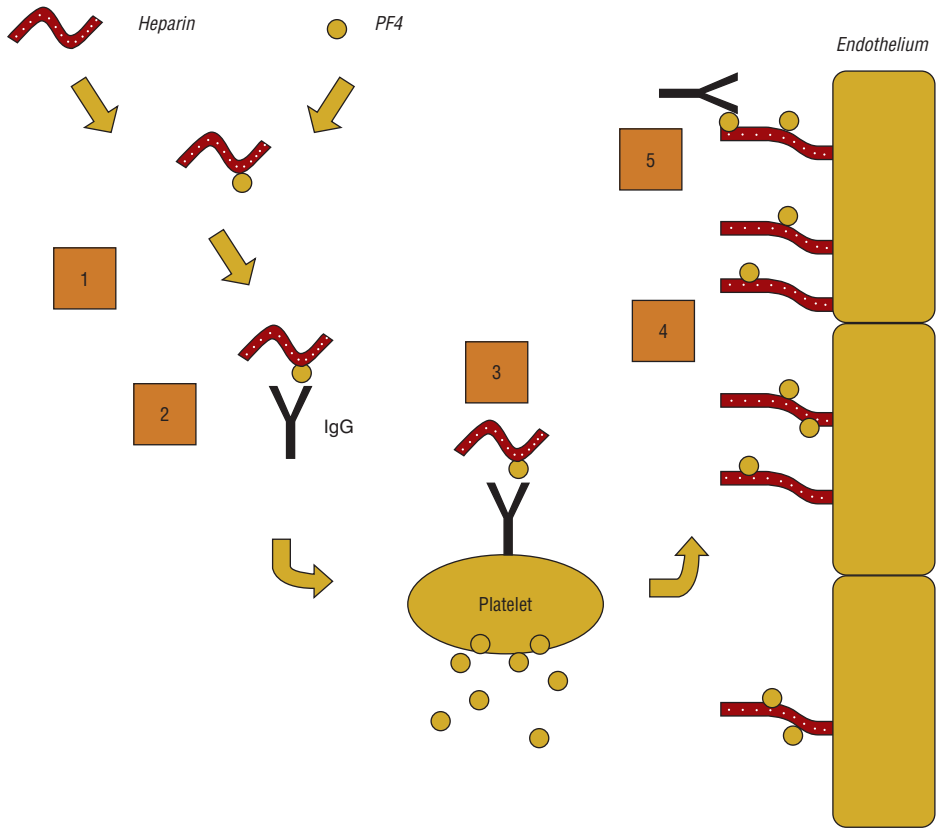

FIGURE 26-11. Pathogenesis of heparin-induced thrombocytopenia. (IgG, immunoglobulin G; PF4, platelet factor 4.)

release of tissue factor. The net result of this cascade of events is an increased risk of thrombotic events secondary to platelet activation, endothelial damage, and thrombin generation despite moderate to severe thrombocytopenia. Antibodies to the heparin/PF4 complex are transient, and they have been reported to disappear from the circulation within a median of 85 days.[31,44]

CLINICAL PRESENTATION AND DIAGNOSIS OF HIT

Thrombotic complications are the most common clinical sequelae of HIT (see Table 26–25).[31,44] The incidence of thrombosis can be as high as 50% in those patients with laboratory-confirmed immune mediated thrombocytopenia. Thrombosis may occur in patients with seemingly mild thrombocytopenia but platelet counts invariably have dropped more than 50% from baseline. This syndrome is poorly recognized and many, perhaps most, patients diagnosed with HIT initially present with thrombosis. Even among those diagnosed prior to the development of thrombosis, the prognosis is poor. In patients diagnosed with HIT without thrombosis and managed only by discontinuation of UFH, the risk of symptomatic thrombosis is 25% to 50%, and fatal thrombosis is 5%.[31,44]

Thrombotic risk is 30 times higher in patients with HIT compared with control populations.[89] Venous thrombosis is the most common thrombotic complication associated with HIT and most patients develop proximal DVT. PE occurs in 25% of patients with thrombotic complications and contributes significantly to mortality. Arterial thrombosis occurs less commonly.[31,88] Limb artery occlusion, stroke, and myocardial infarction are the most commonly reported arterial events. HIT has also been linked with atypical manifestations such as skin necrosis, venous limb gangrene, and anaphylactic-type reactions after intravenous bolus of UFH. Heparin-induced skin lesions occur in 10% to 20% of patients with HIT. Lesions range from painful, localized erythematous plaques to widespread dermal necrosis. Amputation in such cases is frequently required. Mortality from HIT may be as high as 50% in patients with acute thrombosis. The relatively high frequency of thrombotic complications and poor outcomes associated with HIT emphasize the need for prompt recognition and diagnosis.[31,44]

The diagnosis of immune-mediated HIT is made based on clinical findings supplemented by laboratory tests confirming the presence of antibodies to heparin or platelet activation induced by heparin.[31,44] Thrombocytopenia is the most common initial event suggesting the diagnosis of HIT. New thrombosis shortly after the development of thrombocytopenia is a distinguishing feature in nearly half of all patients with HIT. The time course and magnitude of thrombocytopenia distinguish immune-mediated HIT from HAT. Acute thrombosis and skin lesions may also occur prior to the development of overt thrombocytopenia. HIT should immediately be suspected when these events occur in any patient on UFH or LMWH therapy.

Laboratory testing must be performed to confirm the diagnosis of HIT.[31,88] Laboratory testing is very helpful in patients with only mild to moderate thrombocytopenia in whom HIT is suspected. Two types of assays are available to detect the presence of heparin antibodies. Platelet activation assays, also known as functional assays, confirm in vitro platelet activation in the presence of therapeutic heparin levels. Functional assays include the heparin-induced platelet-activation assay, the serotonin release assay, and the platelet-aggregation assay. The heparin-induced platelet-activation assay and serotonin release assay tests have higher sensitivity and specificity than the platelet-aggregation assay but are technically more difficult to perform. Antigen assays that detect the presence of specific antibodies against the heparin–PF4 complex using enzyme-linked immunosorbent assays are also available. These tests have reasonably high sensitivity and specificity. The optimal test for laboratory confirmation of immune-mediated HIT is

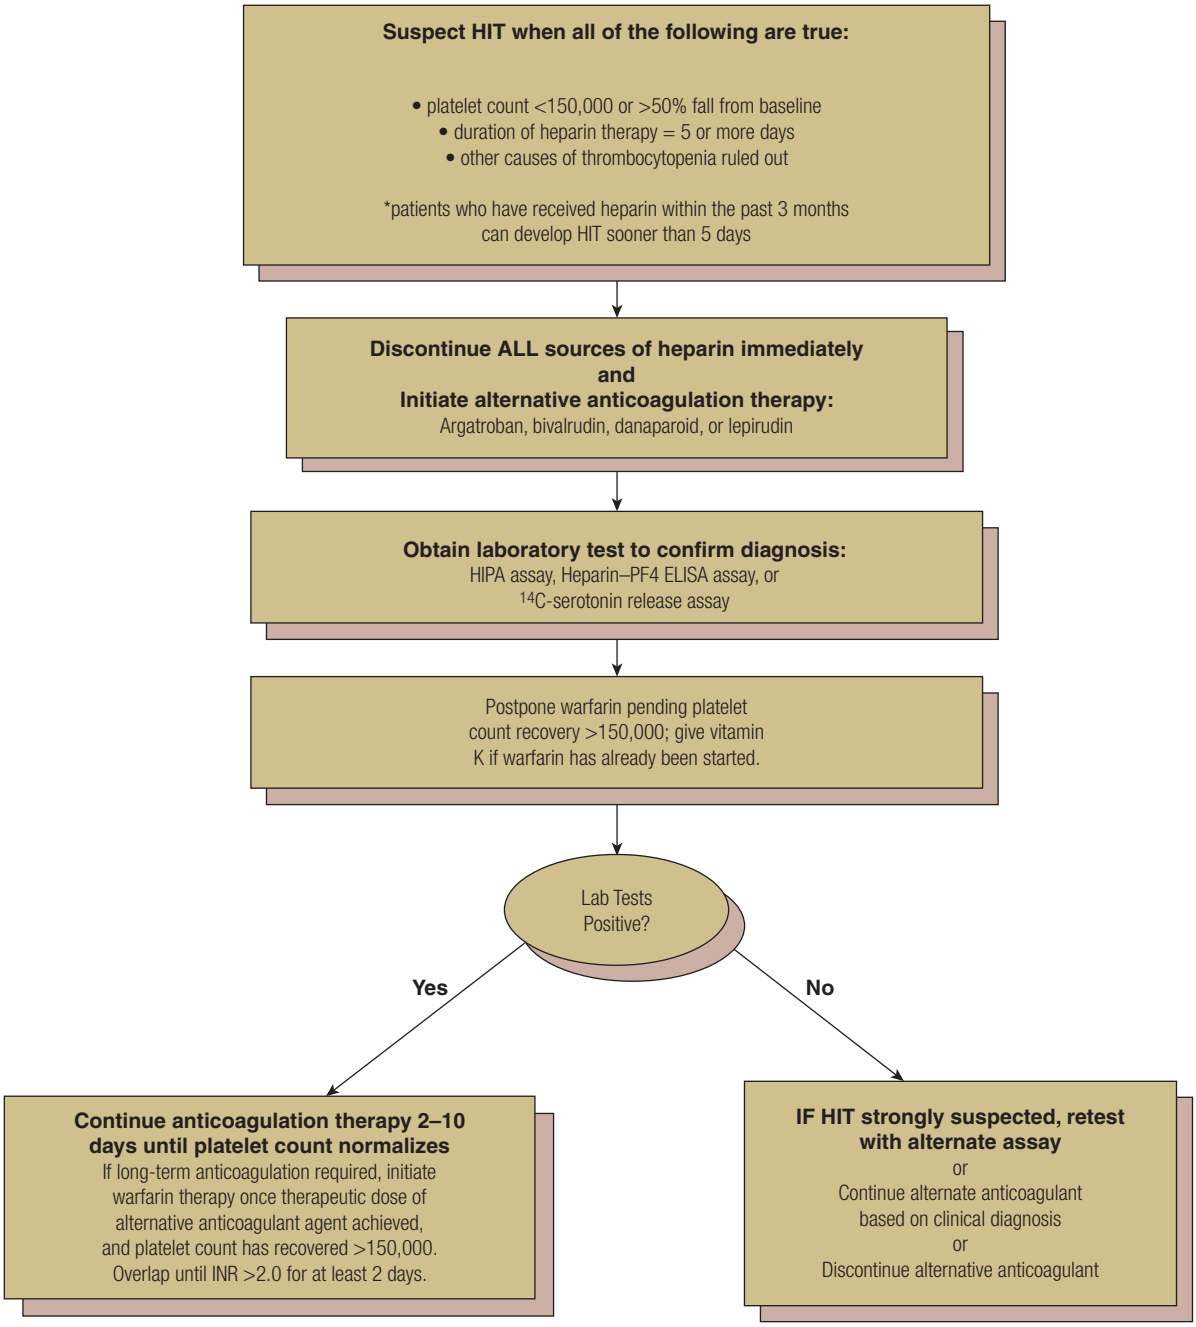

FIGURE 26-12. Treatment of heparin-induced thrombocytopenia (HIT). (HIPA assay, heparin-induced platelet activation assay; ELISA, enzyme-linked immunosorbent assay; INR, international normalized ratio.)

unclear. The most readily available test with the greatest sensitivity and specificity should be used. The combined use of functional and enzyme-linked immunosorbent assays may reduce false-negative results. When results of one test are negative or indeterminate in patients suspected of HIT, another test should be considered.

GENERAL APPROACHES TO THE TREATMENT OF HIT

The goal of therapy in patients with HIT is to reduce the thrombosis risk by decreasing thrombin generation and platelet activation. The 8th ACCP Consensus Conference on Antithrombotic Therapy has established recommendations for the treatment of HIT.[31] Once the diagnosis of HIT is established or strongly suspected, all sources of heparin, including heparin flushes, should be discontinued and an alternative anticoagulant agent should be initiated (Fig. 26–12).[31,44] Even in the absence of thrombosis, patients with HIT are at extremely high risk for subsequently developing serious thrombotic complications without treatment. Because the time required for diagnostic laboratory results to be reported can be prolonged, it is crucial that alternate anticoagulant agents be initiated in a timely fashion to prevent new thrombosis. Anticoagulant agents that rapidly inhibit thrombin activity and are devoid of significant cross-reactivity with heparin–PF4 antibodies are the drugs of choice for the management of HIT (Table 26–26). In cases of severe or life-threatening thrombosis, surgical extraction of thrombi may be required. Limited data exists regarding the use of thrombolytic therapy in severe HIT with thrombosis. The use of warfarin for long-term anticoagulation in patients with HIT and thrombosis is recommended, but warfarin should

TABLE 26-26 Recommended Dose and Monitoring Parameters for Direct Thrombin Inhibitors to Treat Heparin-Induced Thrombocytopenia

Agent Dose	Manufacturer Recommended Dose	Monitoring Parameters	Clinical Considerations
Lepirudin	0.4 mg/kg (up to 110 kg) slow IV bolus[a] (can also be given without bolus), followed by 0.15 mg/kg/h (up to 110 g) IV infusion[b] **Guidelines recommended dose[c]** Omit initial IV bolus or give at reduced dose of 0.2mg/kg if life-threatening thrombosis; The highest starting infusion rate should not exceed 0.1mg/kg/h	Obtain baseline PT, aPTT, CBC, Scr Check aPTT 2 hours after initiation and each dose change and adjust dose to achieve aPTT 1.5–2.5 times control. Once stabile, monitor aPTT every 12 h	Dose must be reduced in patients with renal impairment; avoiding the bolus dose may reduce the risk of accumulation and may reduce the risk of anaphylaxis; antihirudin antibodies can occur in 40–60% of patients and can lead to reduced clearance. Concomitant warfarin requires dose adjustment
Argatroban	2 mcg/kg/min continuous IV infusion (no bolus); maximum infusion 10 mcg/kg/min	Obtain baseline PT, aPTT, CBC. Monitor aPTT 2 hours after initiation and each dose change and adjust dose to achieve aPTT of 1.5–3 times control (max. 100 s)	Dose reduction is necessary for those patients with hepatic impairment and in critically ill; will cause significant elevation in PT/INR; concurrent warfarin therapy requires special management (when INR >4, argatroban therapy should be withheld and the INR rechecked to determine if it is therapeutic)
Bivalirudin	0.15–0.20 mg/kg/h IV infusion (no bolus); approved dose for PCI: 0.75 mg IV bolus, followed by 1.75 mg/kg/h infusion up to 4 hours	Obtain baseline PT, aPTT, CBC, Scr Check aPTT 2 hours after initiation and adjust dose to achieve aPTT 1.5–2.5 times control	Not FDA approved for treatment of HIT

[a] Bolus dose is not advised in patients with renal impairement.

[b] Dose in isolated HIT: no bolus, 0.1 mg/kg/h infusion with aPTT adjusted to 1.5–2.0 times control.

[c] Clinical guidelines and more current data[31] suggest lower dose requirements for lepirudin compared to manufacturer recommended doses due to concern of heightened bleeding complications with the higher manufacturer recommended doses.

aPTT, activated partial thromboplastin time; CBC, complete blood cell count; HIT, heparin-induced thrombocytopenia; INR, international normalized ratio; IV, intravenous; PCI, percutaneous coronary intervention; PT, prothrombin time; Scr, serum creatinine.

only be initiated after substantial platelet count recovery has been documented (e.g., >150,000/mm^3). In addition, great care must be taken when initiating warfarin in these patients as the risk of inducing further thrombosis secondary to inhibition of proteins C and S is possible.[31,44]

PHARMACOLOGIC TREATMENT OPTIONS

DTIs are the drugs of choice for the treatment of HIT with or without thrombosis (see Table 26–26).[31] Three DTIs are currently available in the United States for the treatment of patients with HIT—lepirudin, argatroban, and bivalirudin—but only the first two are FDA approved for this indication.[43,50] For the treatment of HIT, lepirudin and argatroban are administered by intravenous infusion and should be titrated based on aPTT testing. The comparative efficacy of these agents has not been formally evaluated, and they are considered equally suitable for the initial treatment of HIT. Some clinicians prefer argatroban because it has a shorter half-life, modest bleeding risk, and lower cost when compared to lepirudin.[90] Because of a short half -life, low immunogenicity, minimal effect on INR, and enzymatic metabolism, bivalirudin appears to be a promising alternative for treatment of HIT. However, to date, efficacy data is based only on case series.[48] Given fondaparinux is devoid of in vitro cross-reactivity to HIT antibodies, does not interfere with PT/INR measurement, and has enjoyed favorable experience in a few HIT case reports, it is a promising alternative for the management of HIT.[91] Further study is required, however, as fondaparinux has also been associated with HIT in rare cases.[38] Patient-related factors, such as the presence of renal or hepatic dysfunction, drug-specific features such as prior exposure to lepirudin, as well as institutional preference, availability, and cost should be used to determine the most appropriate agent. LMWHs are not recommended for use in HIT because they have nearly 100% cross-reactivity with heparin antibodies by in vitro testing.[31]

The use of warfarin during the initial treatment of HIT is potentially dangerous.[31,44] The rapid reduction in protein C concentrations induced early in the course of warfarin therapy further increases the risk thrombosis in patients with HIT. This concern is supported by the observation that several patients with HIT have developed venous limb gangrene and warfarin-induced skin necrosis when treated with warfarin. Patients with venous limb gangrene had relatively high INRs after the initiation of warfarin therapy and presumably had rapid depletion of protein C but persisting thrombin generation. Therefore, warfarin is contraindicated as monotherapy for the initial treatment of patients diagnosed with HIT. However, patients with HIT and thrombosis requiring long-term anticoagulation can be treated with warfarin if therapy is appropriately timed and carefully initiated. A conservative approach is to withhold warfarin until the patient is stabilized and platelet counts have substantially recovered at least above 100,000 mm^3, and preferably above 150,000 mm^3. If warfarin has already been initiated when HIT is diagnosed, reversing therapy with vitamin K (5–10 mg either IV or oral) is recommended. This may prevent the development of further thrombotic adverse events caused by protein C depletion. Warfarin can be reinitiated once platelet counts have been recovered (>150,000 mm^3) but it should be overlapped with a DTI for a minimum of 5 days and until the full anticoagulant effect of warfarin has been achieved (i.e., INR within the therapeutic range for at least 2 consecutive days). Initial doses of warfarin greater than 5 mg should be strictly avoided in these patients.[31,44]

The management of pregnant patients with a history of HIT requiring anticoagulation therapy presents a challenge. Both UFH and LMWH are the anticoagulants of choice for pregnant patients requiring anticoagulation therapy. Women who develop HIT during pregnancy or who have a recent history of HIT (e.g., < 3 months) cannot use UFH or LMWH safely. Limited evidence exists for the use of DTIs in pregnancy. Lepirudin is known to cross the placenta; however, case reports suggest it may be safe

for the management of HIT with thrombosis in pregnancy.[92] Danaparoid, a low-molecular-weight heparinoid not available in the United States that does not cross the placenta has also been investigated as a potential anticoagulant option in pregnant patients with HIT.[16] Limited case reports suggest that fondaparinux may also be a future potential alternative in pregnant patients.[93]

EVALUATION OF THERAPEUTIC OUTCOMES

The appropriate duration of therapy in patients with HIT will depend on whether the patient had a thrombotic event. HIT patients without thrombosis should continue therapeutic doses of alternative anticoagulant agents until platelet counts have normalized. Platelet counts should be monitored frequently, and patients should be watched closely for the development of new thrombosis after starting an alternate anticoagulant. Patients with thrombosis, either at the time of presentation or following the diagnosis of HIT, should receive therapy with an alternative anticoagulant such as lepirudin or argatroban followed by a transition to warfarin after the platelet count has recovered to >150,000 mm^3. Warfarin therapy is usually continued for at least 6 months, or longer if indicated. The initial anticoagulant used should be continued until the INR is stable and therapeutic for more than two consecutive days. In addition, it is important to clearly document the occurrence of immune-mediated HIT in the patient's medical record and educate the patient regarding this adverse effect. Future use of UFH, particularly in the next 3 to 6 months, should be strictly avoided. As PF4–heparin antibodies are transient and usually cleared within 3 months, patients with a history of HIT should be tested for HIT antibodies prior to any future use of UFH. Although there are few data regarding the use if UFH in patients with a remote history of HIT, these patients should receive alternative anticoagulant agents for most indications until more rigorous data are available.[31,44]

NATIONAL QUALITY INITIATIVES

Despite the fact that several clinical interventions are known to be effective in preventing and treating VTE, adherence with various consensus guidelines regarding thrombophrophylaxis remains alarmingly low.[2] Although preventing VTE is a significant patient safety issue, there is little public awareness of the life-threatening nature of DVT and PE. A survey conducted on behalf of the American Public Health Association suggests that 75% of Americans have little or no awareness of DVT, and less than one half of respondents could identify any risk factors associated with its development.[94] Recognizing the lack of public awareness, several organizations have focused on increasing consumer knowledge of the risks, signs, and symptoms of VTE through increased media visibility.

Given the number and variety of clinical conditions or circumstances that place individuals at risk for VTE, improvements in VTE prevention and care have the potential to benefit many patients. Over the past decade, the focus on quality healthcare has been emphasized by the call to accountability through the Joint Commission's Agenda for Change, the Institute of Medicine's report on medical errors, the National Quality Forum's endorsed safe practices, the Leapfrog Group, and the demand for value by healthcare consumers (Table 26–27).[95,96] The National Quality Forum (NQF) has developed national consensus standards for VTE prevention and treatment that will be applicable to a variety of healthcare settings.[96] The outcomes of this effort will provide a framework for measuring the effective screening, prevention, and treatment of VTE. NQF's recommendations include developing organizational policies that address staff education, treatment protocols, and adherence measurements to improve VTE prevention in the hospital. The ultimate goal of the NQF consensus standards is to facilitate early promulgation of VTE policies, risk assessment, prophylaxis, diagnosis and treatment services as well as patient education and organizational accountability. To that end, the Joint Commission has developed performance measures to enforce the NQF's recommendations.[95] Four major domains have been identified: risk assessment, prevention, diagnosis, and treatment. Six measures have been selected for implementation as core VTE quality measures. It is expected that compliance and reporting on these measures eventually will be tied to payment from governmental entities like Medicare and Medicaid (Table 26–28).

Hopefully, through the concerted efforts of government and accrediting agencies working with hospitals and other healthcare institutions, the incidence of DVT and PE will begin to fall. Systematic approaches to this problem are needed at every level, starting with increased public and health practitioner awareness, continuing with the uniform use of effective prophylactic strategies in patients at risk, and concluding with greater accountability with precise quality measurements.

TABLE 26-27 Organizations Monitoring Quality Care

The Joint Commission *www.jointcommission.org* A not-for-profit healthcare accreditation organization that issues performance-based standards and assesses organizational compliance to improve patient safety and quality of care.
Leapfrog Group *www.leapfroggroup.org* An initiative of healthcare purchasing organizations seeking improvements in safety, quality, and affordability of healthcare, with funding from the Business Roundtable, Robert Wood Johnson Foundation, and member organizations.
National Quality Forum *www.qualityforum.org* A not-for-profit that develops and implements national strategies for healthcare quality measurement and reporting.

TABLE 26-28 The Joint Commission's Proposed Performance Measures for the Prevention and Treatment of Venous Thrombosis

Number	Description of Proposed Performance Measure
1	Documentation of Venous Thromboembolism Risk Assessment/ Prophylaxis within 24 Hours of Hospital Admission
2	Documentation of Venous Thromboembolism Risk Assessment/ Prophylaxis within 24 Hours of Transfer to ICU
3	Venous Thromboembolism Patients with Overlap of Parenteral and Warfarin Anticoagulation Therapy
4	Venous Thromboembolism Patients Receiving Unfractionated Heparin by Nomogram/Protocol and with Platelet Count Monitoring
5	Venous Thromboembolism Discharge Instructions
6	Incidence of Potentially Preventable Hospital-Acquired Venous Thromboembolism

CHAPTER 27

Stroke

SUSAN C. FAGAN AND DAVID C. HESS

KEY CONCEPTS

1. Stroke is one of the leading killers of individuals worldwide.
2. Stroke can be either ischemic (87%) or hemorrhagic (13%).
3. Transient ischemic attacks (TIAs) require urgent intervention to reduce the risk of stroke, which is known to be highest in the first few days after TIA.
4. Carotid endarterectomy should be performed in ischemic stroke patients with 70% to 99% stenosis of the ipsilateral carotid artery, provided that it is done in an experienced center.
5. Early reperfusion (<4.5 hours from onset) with tissue plasminogen activator (t-PA) has been shown to reduce the ultimate disability caused by ischemic stroke.
6. Antiplatelet therapy is the cornerstone of antithrombotic therapy for the secondary prevention of ischemic stroke.
7. Warfarin is the drug of choice for secondary prevention of cardioembolic stroke.
8. Blood pressure lowering is effective in both the primary and secondary prevention of both ischemic and hemorrhagic stroke regardless of blood pressure.
9. Blood pressure lowering in the acute stroke period (first 7 days) can result in decreased cerebral blood flow and worsened symptoms.
10. Statin therapy is recommended for all ischemic stroke patients, regardless of baseline cholesterol, to reduce recurrent vascular events.

1 Stroke is the leading cause of disability among adults and the third leading cause of death in the United States, behind cardiovascular disease and all cancers. Despite a 30% reduction in stroke mortality between 1995 and 2005, stroke occurs in the United States at a rate of almost 800,000 per year and results in 150,000 deaths.[1] Aggressive efforts to organize stroke care at the local and regional levels and increased utilization of evidence-based recommendations and national guidelines may have contributed to the improved outcomes.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

EPIDEMIOLOGY

There are currently 6.5 million stroke survivors in the United States, and stroke is the leading cause of adult disability.[1] Of those free of the diagnosis of stroke or TIA, however, almost 20% of individuals over the age of 45 years reported at least one stroke symptom,[2] suggesting rampant underdiagnosing. Owing in part to the need for expensive posthospitalization rehabilitation and nursing home care, the annual cost of stroke in the United States is estimated to be $69 billion.[1] Current projections are that death caused by stroke will increase exponentially in the next 30 years owing to aging of the population and our inability to control risk factors.[3]

African Americans have stroke rates that are twice those of whites, and the difference is exaggerated at younger ages.[1] In addition, geographic disparity in stroke incidence exists, such that many states in the southeastern United States have stroke mortality rates more than twice that of the national average.[1]

ETIOLOGY AND CLASSIFICATION

2 Stroke can be either ischemic or hemorrhagic (87% and 13%, respectively, of all strokes in the 2009 American Heart Association report).[1,4] A classification of stroke by mechanism is given in Figure 27–1. Hemorrhagic strokes include subarachnoid hemorrhage, intracerebral hemorrhage, and subdural hematomas. Subarachnoid hemorrhage occurs when blood enters the subarachnoid space (where cerebrospinal fluid is housed) owing to either trauma, rupture of an intracranial aneurysm, or rupture of an arteriovenous malformation (AVM). By contrast, intracerebral hemorrhage occurs when a blood vessel ruptures within the brain parenchyma itself, resulting in the formation of a hematoma. These types of hemorrhages very often are associated with uncontrolled high blood pressure and sometimes antithrombotic or thrombolytic therapy. Subdural hematomas refer to collections of blood below the dura (covering of the brain), and they are caused most often by trauma. Hemorrhagic stroke, although less common, is significantly more lethal than ischemic stroke, with 30-day case-fatality rates that are two to six times higher.[5,6]

Ischemic strokes are caused either by local thrombus formation or by embolic phenomena, resulting in occlusion of a cerebral artery. Atherosclerosis, particularly of the cerebral vasculature, is a causative factor in most cases of ischemic stroke, although 30% are cryptogenic. Emboli can arise from either intra- or extracranial arteries (including the aortic arch) or, as is the case in 20% of all ischemic strokes, the heart. Cardiogenic embolism is presumed to have occurred if the patient has concomitant atrial fibrillation, valvular heart disease, or any other condition of the heart that can lead to clot formation.[7] Distinguishing between cardiogenic embolism and other causes of ischemic stroke is important in determining long-term pharmacotherapy in a given patient.

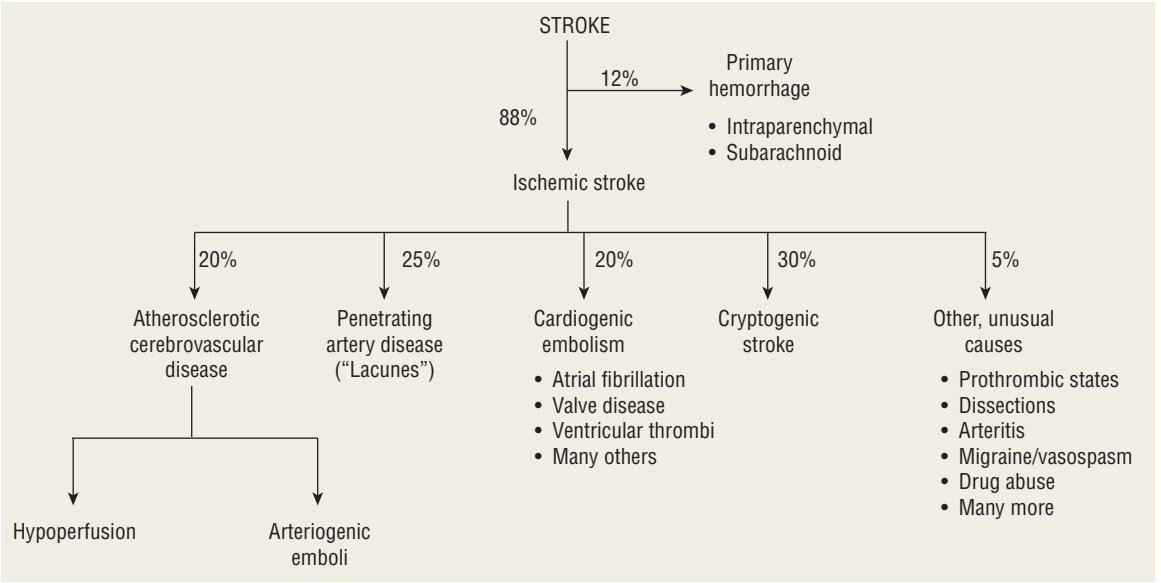

FIGURE 27-1. A classification of stroke by mechanism with estimates of the frequency of various categories of abnormalities. Approximately 30% of ischemic strokes are cryptogenic.

RISK FACTORS

Risk factors for stroke can be subdivided into nonmodifiable, modifiable, and potentially modifiable. In addition, risk factors can be either well documented or less well documented.[8] The main risk factors of stroke are listed in Table 27–1. Recommendations for risk factor reduction aggressively target the modifiable, well-documented risk factors, even in individuals with nonmodifiable risk.[8] The nonmodifiable risk factors are age, race, sex, low birth weight, and family history. An individual's risk of having a stroke increases substantially as he or she ages, with a doubling of risk for each decade older than 55 years of age. African Americans, Asian-Pacific Islanders, and Hispanics experience higher death rates than their Caucasian counterparts.[1,4] Men are at a higher risk of stroke than women when matched for age, but women who suffer from a stroke are more likely to die from it.[1]

TABLE 27-1 Risk Factors for Ischemic Stroke

Nonmodifiable risk factors or risk markers
Age
Gender
Race
Family history of stroke
Low birth weight
Modifiable, well documented
Hypertension–single most important risk factor for ischemic stroke
Atrial fibrillation–most important and treatable cardiac cause of stroke
Other cardiac diseases
Diabetes–independent risk factor
Dyslipidemia
Cigarette smoking
Alcohol
Sickle cell disease
Asymptomatic carotid stenosis
Postmenopausal hormone therapy
Lifestyle factors–associated with stroke risk
Obesity
Physical inactivity
Diet
Potentially modifiable, less well documented
Oral contraceptives
Migraine
Drug and alcohol abuse
Hemostatic and inflammatory factors–fibrinogen linked to increased risk
Homocysteine
Sleep-disordered breathing

Goldstein LB, Adams R, Alberts MJ, et al. Primary prevention of ischemic stroke: A guideline from the American Heart Association/American Stroke Association Stroke Council: Cosponsored by the Atherosclerotic Peripheral Vascular Disease Interdisciplinary Working Group; Cardiovascular Nursing Council; Clinical Cardiology Council; Nutrition, Physical Activity, and Metabolism Council; and the Quality of Care and Outcomes Research Interdisciplinary Working Group. Stroke 2006;37:1583–1633. Source: American Heart Association, Inc.

The most common modifiable, well-documented risk factors for stroke include hypertension, cigarette smoking, diabetes, atrial fibrillation, and dyslipidemia. The treatment of hypertension, beginning in the mid-20th century, is thought to be primarily responsible for the drastic reduction in stroke death rates between 1950 and 1980 in the United States.[4] A second very important risk factor for stroke is cardiac disease. Patients with coronary artery disease, congestive heart failure, left ventricular hypertrophy, and especially atrial fibrillation are at increased risk of stroke.[8,9] In fact, the presence of atrial fibrillation is one of the most potent risk factors for ischemic stroke, with stroke rates from 5% to 20% per year depending on the patient's comorbid conditions.[10,11] Other known risk factors for atherosclerosis are also known to place patients at risk of stroke. Diabetes mellitus, dyslipidemia, and cigarette smoking are known atherogenic states that lead to cerebrovascular disease and ischemic stroke.[8,9,12]

PATHOPHYSIOLOGY

ISCHEMIC STROKE

In carotid atherosclerosis, progressive accumulation of lipids and inflammatory cells in the intima of the affected arteries, combined with hypertrophy of arterial smooth muscle cells, results in plaque formation. Eventually, sheer stress may result in plaque rupture, collagen exposure, platelet aggregation, and clot formation. The clot can remain in the vessel, causing local occlusion, or travel distally as an embolism, eventually lodging downstream in a cerebral vessel. In the case of cardiogenic embolism, stasis of blood in the atria or ventricles of the heart leads to the formation of local clots that can become dislodged and travel directly through the aorta to the cerebral circulation. The final result of both thrombus formation

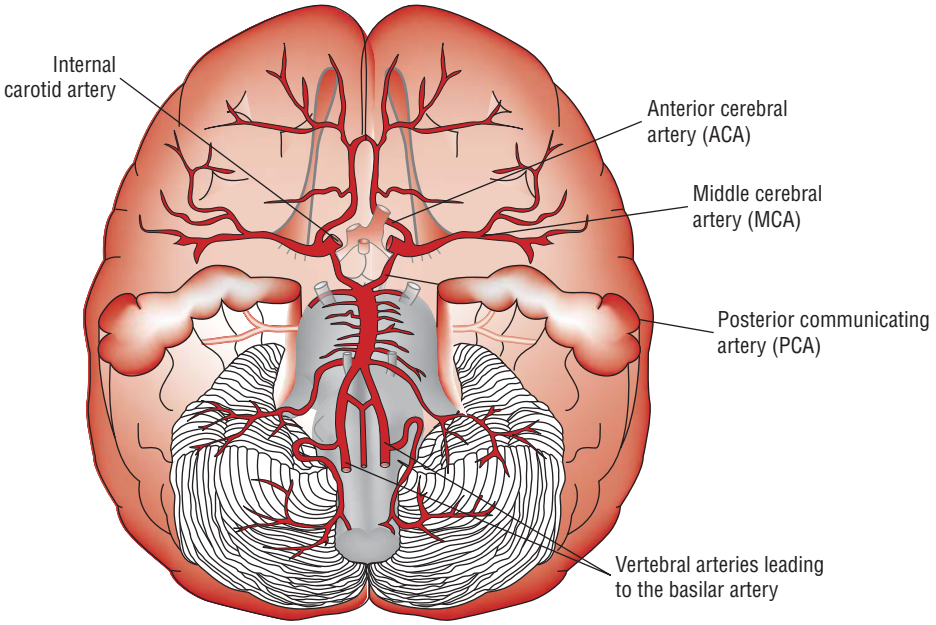

FIGURE 27-2. Main arterial blood supply to the brain.

and embolism is an arterial occlusion, decreasing cerebral blood flow and causing ischemia distal to the occlusion.[13]

Normal cerebral blood flow averages 50 mL/100 g per minute, and this is maintained over a wide range of blood pressures (mean arterial pressures of 50 to 150 mm Hg) by a process called *cerebral autoregulation.* Cerebral blood vessels dilate and constrict in response to changes in blood pressure, but this process can be impaired by atherosclerosis, chronic hypertension, and acute injury, such as stroke. When local cerebral blood flow decreases below 20 mL/100 g per minute, ischemia ensues, and when further reductions below 12 mL/100 g per minute persist, irreversible damage to the brain occurs, which is called *infarction.* Tissue that is ischemic but maintains membrane integrity is referred to as the ischemic *penumbra* because it usually surrounds the infarct core. This penumbra is potentially salvageable through therapeutic intervention.

Reduction in the provision of nutrients to the ischemic cell eventually leads to depletion of the high-energy phosphates (e.g., adenosine triphosphate [ATP]), accumulation of extracellular potassium, intracellular sodium, and water, leading to cell swelling and eventual lysis. The increase in intracellular calcium that follows results in the activation of lipases, proteases, and endonucleases and the release of free fatty acids from membrane phospholipids. The critical step is damage to the mitochondria. In addition, there is a release of excitatory amino acids, such as glutamate and aspartate, that perpetuates the neuronal damage and the accumulation of free fatty acids, including arachidonic acid, and results in the formation of prostaglandins, leukotrienes, and free radicals. In ischemia, the magnitude of free-radical production overwhelms normal scavenging systems, leaving these reactive molecules to attack cell membranes and contribute to the mounting intracellular acidosis. All these events occur within 2 to 3 hours of the onset of ischemia and contribute to the ultimate cell death.[13]

Later targets for intervention in the pathophysiologic process involved after cerebral ischemia include the influx of activated inflammatory cells, starting from 2 hours after the onset of ischemia and lasting for several days. Also, the initiation of apoptosis, or programmed cell death, is thought to occur many hours after the acute insult and can interfere with recovery and repair of brain tissue.[14]

HEMORRHAGIC STROKE

The pathophysiology of hemorrhagic stroke is not as well studied as that of ischemic stroke. However, it is known that the presence of blood in the brain parenchyma causes damage to the surrounding tissue through the mechanical effect it produces (mass effect) and the neurotoxicity of the blood components and their degradation products.[5,6] Approximately 30% of intracerebral hemorrhages continue to enlarge over the first 24 hours, most within 4 hours, and clot volume is the most important predictor of outcome, regardless of location.[15] Hemorrhage volumes >60 mL are associated with 71% to 93% mortality at 30 days.[5,6] Much of the early mortality of hemorrhagic stroke (up to 50% at 30 days) is caused by the abrupt increase in intracranial pressure that can lead to herniation and death.[1] There is also evidence to support that both early and late edema contributes to worsened outcome after intracerebral hemorrhage.[6]

CLINICAL PRESENTATION (INCLUDING DIAGNOSTIC CONSIDERATIONS)

Stroke is a term used to describe an abrupt-onset focal neurologic deficit that lasts at least 24 hours and is of presumed vascular origin. A transient ischemic attack (TIA) is the same but lasts less than 24 hours and usually less than 30 minutes. The abrupt onset and the duration of the symptoms are determined through the history. The use of sensitive imaging techniques (magnetic resonance imaging [MRI] with diffusion-weighted imaging [DWI]) has revealed that symptoms lasting more than 1 hour and less than 24 hours, are associated with infarction, making TIA and minor stroke clinically indistinguishable. The location of the central nervous system injury and its reference to a specific arterial distribution in the brain are determined through the neurologic examination and confirmed by imaging studies such as computed tomography (CT) scanning and MRI. The main arterial supply to the brain is illustrated in Figure 27–2. Further diagnostic tests are performed to identify the cause of the patient's stroke and to design appropriate therapeutic strategies to prevent further events.[16]

CLINICAL PRESENTATION OF STROKE

General

- The patient may not be able to reliably report the history owing to cognitive or language deficits. A reliable history may have to come from a family member or another witness.

Symptoms

- The patient may complain of weakness on one side of the body, inability to speak, loss of vision, vertigo, or falling. Ischemic stroke is not usually painful, but patients may complain of headache, and with hemorrhagic stroke, it can be very severe.

Signs

- Patients usually have multiple signs of neurologic dysfunction, and the specific deficits are determined by the area of the brain involved.
- Hemi- or monoparesis occurs commonly, as does a hemisensory deficit.
- Patients with vertigo and double vision are likely to have posterior circulation involvement.
- Aphasia is seen commonly in patients with anterior circulation strokes.
- Patients may also suffer from dysarthria, visual field defects, and altered levels of consciousness.

Laboratory Tests

- Tests for hypercoagulable states (protein C deficiency, antiphospholipid antibody) should be done only when the cause of the stroke cannot be determined based on the presence of well-known risk factors for stroke. Protein C, protein S, and antithrombin III are best measured in the "steady state," not in the acute stage. Antiphospholipid antibodies as measured by anticardiolipin antibodies, β_2-glycoprotein I, and lupus anticoagulant screen are of higher yield than protein C, protein S, and antithrombin III but should be reserved for patients who are young (<50 years of age), have had multiple venous/arterial thrombotic events, or have livedo reticularis (a skin rash).

Other Diagnostic Tests

- CT scan of the head will reveal an area of hyperintensity (white) in the area of hemorrhage and will be normal or hypointense (dark) in the area of infarction. The CT scan may take 24 hours (and rarely longer) to reveal the area of infarction.
- MRI of the head will reveal areas of ischemia with higher resolution and earlier than the CT scan. Diffusion-weighted imaging (DWI) will reveal an evolving infarct within minutes.
- Carotid Doppler (CD) studies will determine whether the patient has a high degree of stenosis in the carotid arteries supplying blood to the brain (extracranial disease).
- An electrocardiogram (ECG) will determine whether the patient has atrial fibrillation, a potent etiologic factor for stroke.
- Transthoracic echocardiography (TTE) will determine whether valve abnormalities or wall-motion abnormalities are sources of emboli to the brain. A "bubble test" can be done to look for an intraatrial shunt indicating an atrial septal defect or a patent foramen ovale.
- Transesophageal echocardiography (TEE) is a more sensitive test for thrombus in the left atrium. It is effective at examining the aortic arch for atheroma, a potential source of emboli.
- Transcranial Doppler (TCD) will determine whether the patient is likely to have intracranial stenosis (e.g., middle cerebral artery stenosis).

TREATMENT

Stroke

DESIRED OUTCOME

The goals of treatment of acute stroke are (a) to reduce the ongoing neurologic injury and decrease mortality and long-term disability, (b) prevent complications secondary to immobility and neurologic dysfunction, and (c) prevent stroke recurrence.[17–19] Primary prevention of stroke is reviewed elsewhere.[8]

GENERAL APPROACH TO TREATMENT

The initial approach to the patient with a presumed acute stroke is to ensure that the patient is supported from a respiratory and cardiac standpoint and to quickly determine whether the lesion is ischemic or hemorrhagic, based on a CT scan. Ischemic stroke patients presenting within hours of the onset of their symptoms should be evaluated for reperfusion therapy. 3 TIAs also require urgent intervention to reduce the risk of stroke, which is known to be highest in the first few days after TIA.[20] According to the ASA Guidelines, patients with elevated blood pressure should remain untreated unless their blood pressure exceeds 220/120 mm Hg, or they have evidence of aortic dissection, acute myocardial infarction (AMI), pulmonary edema, or hypertensive encephalopathy. However, this level of blood pressure may be too high, and a number of clinical trials are currently testing more aggressive treatment of hypertension in the acute setting. If blood pressure is treated, short-acting parenteral agents, such as labetalol and nicardipine, or nitroprusside, are favored. Current recommendations regarding management of arterial hypertension in stroke patients is given in Table 27–2.[17–19] In patients with subarachnoid hemorrhage, if an aneurysm is found by angiography, endovascular coiling or clipping via a craniotomy should be performed to reduce the risk of rebleeding. In intracerebral hemorrhage, patients may require external ventricular drainage (EVD) if there is intraventricular blood and evolving hydrocephalus (enlargement of the ventricles). Once the patient is out of the hyperacute phase, attention is placed on preventing worsening, minimizing complications, and instituting appropriate secondary prevention strategies. The acute phase of the stroke includes the first week after the event.[17]

NONPHARMACOLOGIC THERAPY

Ischemic Stroke

Surgical interventions in the acute ischemic stroke patient are limited. In certain cases of ischemic cerebral edema owing to a large

TABLE 27-2 Blood Pressure Treatment Guidelines in Acute Ischemic Stroke Patients

Treatment	Received t-PA	Did Not Receive t-PA
None	<180/105	<220/120
Labetalol IV[a] or Nicardipine IV[b]	180–230/105–120	>220/121–140
Nitroprusside[c]	Diastolic >140	Diastolic >140

t-PA, tissue plasminogen activator.
[a]Labetalol IV = 10–20 mg, doubled every 10–20 minutes, to a maximum of 300 mg. Also can use an infusion of 2–8 mg/min.
[b]Nicardipine IV = infusion starting at 5 mg/h up to 15 mg/h.
[c]Nitroprusside IV = infusion starting at 0.5 mcg/kg/min, with continuous arterial blood pressure monitoring.
Adams HP, del Zoppo G, Alberts MJ, et al. Stroke 2007;38:1655–1711. Source: American Heart Association, Inc.

infarction, craniectomy to release some of the rising pressure has been tried. In cases of significant swelling associated with a cerebellar infarction, surgical decompression can be lifesaving. Beyond surgical intervention, however, the use of an organized, multidisciplinary approach to stroke care that includes early rehabilitation has been shown to be very effective in reducing the ultimate disability owing to ischemic stroke. In fact, the use of "stroke units" has been associated with outcomes similar to those achieved with early thrombolysis when compared with usual care.[17]

4 In secondary prevention, carotid endarterectomy of an ulcerated and/or stenotic carotid artery is a very effective way to reduce stroke incidence and recurrence in appropriate patients and in centers where the operative morbidity and mortality are low. In fact, in ischemic stroke patients with 70% to 99% stenosis of an ipsilateral internal carotid artery, recurrent stroke risk can be reduced by up to 48% compared with medical therapy alone when combined with aspirin 325 mg daily.[21] In patients in whom the risk of endarterectomy is thought to be excessive, carotid stenting can be effective in reducing recurrent stroke risk.[22] Carotid endarterectomy remains preferred in elderly patients.[22]

Hemorrhagic Stroke

As in patients with subarachnoid hemorrhage owing to a ruptured intracranial aneurysm, in arteriovenous malformations (AVMs), surgical intervention to either clip or ablate the offending vascular abnormality substantially reduces mortality owing to rebleeding.[23] In the case of primary intracerebral hemorrhage, however, the benefits of surgery are less well documented. Although some patients undergo surgical evacuation of intracerebral hematomas, recommendations are limited to lobar (near the surface) and cerebellar hemorrhages.[6,15] Insertion of an external ventricular drain (EVD) for hydrocephalus and subsequent monitoring of intracranial pressure are done commonly and are the least invasive of the procedures done in these patients.

PHARMACOLOGIC THERAPY

Ischemic Stroke

Drug Treatments of First Choice: Published Guidelines The Stroke Council of the American Stroke Association has created and published guidelines that address the management of acute ischemic stroke.[17] In general, the only two pharmacologic agents with class I recommendations are intravenous t-PA within 4.5 hours of onset and aspirin within 48 hours of onset.

5 Early reperfusion (<4.5 hours from onset) with intravenous t-PA has been shown to reduce the ultimate disability caused by ischemic stroke.[24,25] Caution must be exercised when using this therapy, and adherence to a strict protocol is essential to achieving positive outcomes.[17] The essentials of the treatment protocol can be summarized as (a) stroke team activation, (b) treat as early as possible within 4.5 hours of onset, (c) CT scan to rule out hemorrhage, (d) meet inclusion and exclusion criteria (Table 27–3), (e) administer t-PA 0.9 mg/kg over 1 hour, with 10% given as initial bolus over 1 minute, (f) avoid antithrombotic (anticoagulant or antiplatelet) therapy for 24 hours, and (g) monitor the patient closely for elevated blood pressure, response, and hemorrhage.[17]

Early aspirin therapy has also been shown to reduce long-term death and disability[26,27] but should never be given within 24 hours of the administration of t-PA because it can increase the risk of bleeding in such patients.[17]

The American Heart Association/American Stroke Association (AHA/ASA) guidelines address all pharmacotherapy used in the secondary prevention of ischemic stroke and are updated every 3 years.[28] It is clear that antiplatelet therapy is the cornerstone of antithrombotic therapy for the secondary prevention of ischemic stroke and should be used in noncardioembolic strokes. All three currently used agents, aspirin, clopidogrel, and extended-release dipyridamole plus aspirin (ERDP-ASA), are considered first-line antiplatelet agents.

In patients with atrial fibrillation and a presumed cardiac source of embolism, warfarin is the antithrombotic agent of first choice. Other pharmacotherapy recommended for secondary prevention of stroke includes blood pressure lowering and statin therapy. Current recommendations regarding the acute treatment and secondary prevention of stroke are given in Table 27–4.

TABLE 27-3 Inclusion and Exclusion Criteria for Alteplase Use in Acute Ischemic Stroke[17,25,29]

Inclusion criteria (all YES boxes must be checked before treatment)

YES

- ☐ Age 18 years or older
- ☐ Clinical diagnosis of ischemic stroke causing a measurable neurologic deficit
- ☐ Time of symptom onset well established to be less than 4.5 hours before treatment would begin

Exclusion criteria (all NO boxes must be checked before treatment)

NO

- ☐ Evidence of intracranial hemorrhage on noncontrast head CT
- ☐ Only minor or rapidly improving stroke symptoms
- ☐ High clinical suspicion of subarachnoid hemorrhage even with normal CT
- ☐ Active internal bleeding (e.g., GI/GU bleeding within 21 days)
- ☐ Known bleeding diathesis, including but not limited to platelet count <100,000/mm^3
- ☐ Patient has received heparin within 48 hours and had an elevated APTT
- ☐ Recent use of anticoagulant (e.g., warfarin) and elevated PT (>15 second)/INR
- ☐ Intracranial surgery, serious head trauma, or previous stroke within 3 months
- ☐ Major surgery or serious trauma within 14 days
- ☐ Recent arterial puncture at noncompressible site
- ☐ Lumbar puncture within 7 days
- ☐ History of intracranial hemorrhage, arteriovenous malformation, or aneurysm
- ☐ Witnessed seizure at stroke onset
- ☐ Recent acute myocardial infarction
- ☐ SBP >185 mm Hg or DBP >110 mm Hg at time of treatment

Additional exclusion criteria if within 3-4.5 hours of onset:[29]

- ☐ Age greater than 80 years
- ☐ Current treatment with oral anticoagulants
- ☐ NIH Stroke Scale Score >25 (severe stroke)
- ☐ History of both stroke and diabetes

APTT, activated partial thromboplastin time; CT, computed tomography; DBP, diastolic blood pressure; GI, gastrointestinal; GU, genitourinary; INR, international normalized ratio; PT, prothrombin time; SBP, systolic blood pressure.

GENERAL INFORMATION REGARDING SAFETY AND EFFICACY (INCLUDING PIVOTAL CLINICAL TRIALS)

t-PA

The effectiveness of IV t-PA in the treatment of ischemic stroke was first demonstrated in the National Institutes of Neurologic Disorders and Stroke (NINDS) Recombinant Tissue-Type Plasminogen Activator (rt-PA) Stroke Trial, published in 1995.[24] In 624 patients treated in equal numbers with either t-PA 0.9 mg/kg IV or placebo within 3 hours of the onset of their neurologic symptoms, 39% of the treated patients achieved an "excellent outcome" at 3 months compared with 26% of the placebo patients. An "excellent outcome" was defined as minimal or no disability by several different neurologic scales. This beneficial effect was reported despite a 10-fold increase in the risk of symptomatic intracerebral hemorrhage in the t-PA-treated patients (0.6% vs. 6.4%). Overall

TABLE 27-4 Recommendations for Pharmacotherapy of Ischemic Stroke

	Recommendation	Evidence[a]
Acute treatment	t-PA 0.9 mg/kg IV[7–17] (maximum 90 mg) over 1 hour in selected patients within 3 hours of onset	IA
	t-PA 0.9 mg/kg IV[25,29] (maximum 90 mg) over 1 hour between 3 and 4.5 hours of onset	IB
	ASA 160–325 mg daily[7,17] started within 48 hours of onset	IA
Secondary prevention		
Noncardioembolic	Antiplatelet therapy	IA
	Aspirin 50–325 mg daily[7,28]	IIa A (all three as initial options)
	Clopidogrel 75 mg daily[7,28]	IIb B (over aspirin)
	Aspirin 25 mg + extended-release dipyridamole 200 mg twice daily[7,28]	IIa A (over aspirin)
Cardioembolic (esp. atrial fibrillation)	Warfarin (INR = 2.5)[7,28]	IA
All	Antihypertensive treatment[28]	IA
Previously hypertensive	ACE inhibitor + diuretic[28]	IA
Previously normotensive	ACE inhibitor + diuretic[28]	IIa B
Dyslipidemic	Statin[28]	IA
Normal lipids	Statin[48]	IB

ACE, angiotensin-converting enzymes; ASA, aspirin; INR, international normalized ratio; t-PA, tissue plasminogen activator.

[a]Classes and levels of evidence: I, evidence or general agreement that useful and effective; II, conflicting evidence about the usefulness; IIa, weight of evidence in favor of the treatment; IIb, usefulness less well established; III, not useful and maybe harmful. Levels of evidence: A, multiple randomized clinical trials; B, a single randomized trial or nonrandomized studies; C, expert opinion or case studies.[28] (Level A in reference 7–t-PA recommendation–does not require multiple trials, just randomized, well-controlled clinical trial.)

Data from Albers et al.,[7] Adams et al.,[17] Sacco et al.,[28] and Adams et al.[48]

mortality was not significantly different between the two groups (17% with t-PA and 21% with placebo). Patients with very severe symptoms at baseline (National Institutes of Health Stroke Scale [NIHSS] >20) and early ischemic changes on CT scan were shown to be at highest risk for the development of symptomatic intracranial hemorrhage. Even in patients at highest risk for bleeding, however, those receiving t-PA had better outcomes at 90 days than those who received placebo.[24]

Thirteen years after the NINDS trial, the European Cooperative Acute Stroke Study (ECASS) III demonstrated that, even when administered between 3 and 4.5 hours after the onset of symptoms, ischemic stroke patients benefit from t-PA when compared with placebo (52.4% vs. 45.2% excellent outcome; $P = 0.04$).[25] The benefit was less than reported with earlier treatment but the rate of excess hemorrhage was similar, leading to a change in AHA guidelines to recommend extension of the window.[29] An important caveat was that the exclusion criteria for later treatment are more strict and are given in Table 27–3.

Aspirin

The use of early aspirin to reduce long-term death and disability owing to ischemic stroke is supported by two large, randomized clinical trials. In the International Stroke Trial (IST),[27] aspirin 300 mg/day significantly reduced stroke recurrence within the first 2 weeks without effect on early mortality, resulting in a significant decrease in death and dependency at 6 months. In the Chinese Acute Stroke Trial (CAST),[26] aspirin 160 mg/day reduced the risk of recurrence and death in the first 28 days, but long-term death and disability were not different than with placebo. In both trials, a small but significant increase in hemorrhagic transformation of the infarction was demonstrated. Overall, the beneficial effects of early aspirin have been embraced and adopted into clinical guidelines.

Antiplatelet Agents

All patients who have had an acute ischemic stroke or TIA should receive long-term antithrombotic therapy for secondary prevention.[28] 6 In patients with noncardioembolic stroke, this will be some form of antiplatelet therapy. In a recent meta-analysis, the overall benefit of antiplatelet therapy in patients with atherothrombotic disorders was estimated to be 22%.[30] Aspirin is the best-studied of the available agents and, until recently, was considered the sole first-line agent. However, published literature has supported the use of clopidogrel and the combination product ERDP-ASA as additional first-line agents in secondary stroke prevention.

The efficacy of clopidogrel as an antiplatelet agent in atherothrombotic disorders was demonstrated in the Clopidogrel versus Aspirin in Patients at Risk of Ischemic Events (CAPRIE) trial.[31] In this study of more than 19,000 patients with a history of either myocardial infarction (MI), stroke, or peripheral arterial disease (PAD), clopidogrel 75 mg/day was compared with aspirin 325 mg/day for its ability to decrease MI, stroke, or cardiovascular death. In the final analysis, clopidogrel was slightly (8% relative risk reduction [RRR]) more effective than aspirin ($P = 0.043$) and had a similar incidence of adverse effects. It is not associated with the blood dyscrasias (neutropenia) common with its congener, ticlopidine, and is used widely in patients with atherosclerosis.

In the European Stroke Prevention Study 2 (ESPS-2), aspirin 25 mg and ERDP 200 mg twice daily were compared alone and in combination with placebo for their ability to reduce recurrent stroke over a 2-year period.[32] In a total of more than 6,600 patients, all three treatment groups were shown to be superior to placebo—aspirin alone (18% RRR), ERDP alone (16% RRR), and the combination (37% RRR). In addition, the combination demonstrated a significant advantage over the aspirin-alone group (23% RRR; $P = 0.006$) and the ERDP-alone group (24% RRR; $P = 0.002$). Headache resulting in discontinuation occurred in approximately 15% of the ERDP groups (four times more common than in the placebo group), and the aspirin-treated patients, even at the low dose of 50 mg/day, experienced significantly more bleeding than the other groups. The European/Australasian Stroke Prevention in Reversible Ischemia Trial (ESPRIT) confirmed the results of ESPS-2, in that the combination of dipyridamole (83% extended release) and aspirin (30–325 mg daily) was more effective than aspirin alone in reducing recurrent stroke.[33] Headache was again an important cause of discontinuation in the ESPRIT trial.

Lastly, in a large, multinational trial (PRoFESS—Prevention Regimen for Effectively Avoiding Second Strokes) comparing ERDP-ASA to clopidogrel, the risk of recurrent stroke was similar for the two antiplatelet agents, but clopidogrel was better tolerated with less bleeding and headache.[34]

Warfarin

7 Warfarin is the treatment of choice for the prevention of stroke in patients with atrial fibrillation.[10,11,35] In patients with atrial fibrillation and a recent history of stroke or TIA, the risk of recurrence places these patients in one of the highest risk categories known. In the European Atrial Fibrillation Trial (EAFT), 669 patients with nonvalvular atrial fibrillation (NVAF) and a prior stroke or TIA were randomized to either warfarin (international normalized ratio [INR] = 2.5–4), aspirin 300 mg/day, or placebo. Patients in the placebo group experienced stroke, MI, or vascular death at a rate of

17% per year compared with 8% per year in the warfarin group and 15% per year in the aspirin group. This represents a 53% reduction in risk with anticoagulation.[10] Subsequent studies in the primary prevention of stroke in patients with NVAF have demonstrated that targeting an international normalization ratio (INR) of 2.5 prevents stroke with the lowest bleeding risk (Stroke Prevention in Atrial Fibrillation [SPAF III]); therefore, a target INR of 2.5 is recommended in the secondary prevention of stroke.[11,35] The emergence of orally active direct thrombin inhibitors (dabigatran) may challenge the favored position of warfarin for stroke prevention in atrial fibrillation.[36]

Use of warfarin in the secondary prevention of noncardioembolic stroke was addressed in the Warfarin Aspirin Recurrent Stroke Study.[37] In 2,206 patients with recent stroke, warfarin (INR = 1.4–2.8) was not superior to aspirin 325 mg/day in the prevention of recurrent events. Further data from the Warfarin-Aspirin in Intracranial Disease (WASID) trial demonstrated that aspirin therapy was as effective and safer than warfarin in patients with intracranial stenosis.[38] These studies led most clinicians to abandon the practice of using warfarin in all but patients with cardioembolic sources of emboli, mainly atrial fibrillation.

Blood Pressure Lowering

8 Elevated blood pressure is very common in ischemic stroke patients, and treatment of hypertension in these patients is associated with a decreased risk of stroke recurrence.[39] In the Perindopril pROtection aGainst REcurrent Stroke Study (PROGRESS), a multinational stroke population (40% Asian) was randomized to receive either blood pressure lowering with the angiotensin-converting enzyme (ACE) inhibitor perindopril (with or without the thiazide diuretic indapamide) or placebo.[40] Treated patients achieved an overall 9 mm Hg systolic and 4 mm Hg diastolic blood pressure reduction, and this was associated with a 28% reduction in stroke recurrence. In the patients who received the combination treatment (clinician's discretion), the average blood pressure lowering achieved was 12 systolic and 5 diastolic mm Hg, and this was associated with an even larger reduction in stroke recurrence (43%). Similar results were achieved in patients with and without hypertension. Based on the results of this study and other evidence of the tolerability and vascular protective properties of the ACE inhibitors, the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC7) and the AHA/ASA guidelines recommend an ACE inhibitor and a diuretic for the reduction of blood pressure in patients with stroke or TIA.[28,41] 9 Early blood pressure lowering can worsen symptoms; therefore, recommendations are limited to patients outside of the acute stroke period (first 7 days).[28] Despite this, there is support for carefully restarting antihypertensive therapy after 24 hours in the acute stroke patient.[17]

Statins

10 The statins have been shown to reduce the risk of stroke by approximately 30% in patients with coronary artery disease and elevated plasma lipids.[42–44] The National Cholesterol Education Program (NCEP) considers ischemic stroke or TIA to be a coronary "equivalent" and has recommended the use of statins to achieve a low-density lipoprotein (LDL) concentration of less than 100 mg/dL.[45] When the Heart Protection Study was published, it provided evidence that simvastatin 40 mg/day reduced stroke risk in high-risk individuals (including patients with prior stroke) by 25% ($P < 0.0001$), even in patients with LDL concentrations of less than 116 mg/dL.[46] The investigators also showed that this practice is extremely safe, with an excess incidence of myopathy of 0.01%. The Stroke Prevention by Aggressive Reduction in Cholesterol (SPARCL) study went one step further by demonstrating, in stroke patients, that atorvastatin 80 mg daily reduced the risk of recurrent stroke by 16% and coronary events by 42% while causing an increase in liver enzymes, but no increase in myopathy.[47] It is now recommended that ischemic stroke patients, regardless of baseline cholesterol, be treated with high-dose statin therapy for secondary stroke prevention.[48]

Heparin for Prophylaxis of Deep-Vein Thrombosis (DVT)

The use of low-molecular-weight heparins or low-dose subcutaneous unfractionated heparin (5,000 units three times daily) can be recommended for the prevention of DVT in hospitalized patients with decreased mobility owing to their stroke and should be used in all but the most minor strokes.[7,17]

ALTERNATIVE DRUG TREATMENTS

Aspirin Plus Clopidogrel

In the Management of ATherothrombosis with Clopidogrel in High-risk patients (MATCH) study, clopidogrel in combination with aspirin 75 mg daily was no better than clopidogrel alone in secondary stroke prevention.[49] However, the combination has been studied in patients with acute coronary syndromes and patients undergoing percutaneous coronary interventions and shown to be significantly more effective than aspirin alone in reducing MI, stroke, and cardiovascular death.[50,51] Also, when clopidogrel was used with aspirin, the risk of life-threatening bleeding increased from 1.3% to 2.6%.[49] In the Clopidogrel for High Atherothrombotic Risk and Ischemic Stabilization, Management and Avoidance (CHARISMA) trial, the combination was again found to significantly increase serious bleeding in a high-risk atherosclerosis population (clinically evident disease or multiple risk factors) with no consistent benefit in terms of preventing vascular events, when compared with aspirin alone.[52] This combination can only be recommended in patients with a recent history of MI or coronary stent placement and only with ultra–low-dose aspirin to minimize bleeding risk.[53]

Angiotensin II Receptor Blockers

Angiotensin II receptor blockers (ARBs) have also been shown to reduce the risk of stroke. In the Losartan Intervention For Endpoint Reduction in Hypertension (LIFE) study, losartan and metoprolol were compared for their ability to reduce blood pressure and prevent cardiovascular events in a group of severely hypertensive patients.[54] Despite similar reductions in blood pressure of approximately 30/16 mm Hg, the losartan group experienced a 24% reduction in the risk of stroke. In a similar study comparing eprosartan to nitrendipine, the ARB eprosartan was superior to the calcium channel blocker in reducing recurrent stroke risk, when equal blood pressure lowering was achieved.[55] Although the use of telmisartan failed to add additional benefit to adequately treated stroke patients in the PRoFESS trial,[34] the ARBs should be considered in patients unable to tolerate ACE inhibitors for blood pressure lowering after acute ischemic stroke.

Heparins

The use of full-dose unfractionated heparin in the acute stroke period has never been proven to positively affect stroke outcome, and it significantly increases the risk of intracerebral hemorrhage.[7,17] Trials of low-molecular-weight heparins or heparinoids have been largely negative and do not support their routine use in stroke patients.[56–58] Other potential but unproven uses for treatment doses of either unfractionated or low-molecular-weight heparins include bridge therapy in patients being initiated on warfarin, carotid dissection, or continuous worsening of ischemia despite adequate antiplatelet therapy.[7]

DRUG CLASS INFORMATION

Aspirin

Aspirin exerts its antiplatelet effect by irreversibly inhibiting cyclooxygenase, which, in platelets, prevents conversion of arachidonic acid to thromboxane A_2 (TXA_2), which is a powerful vasoconstrictor and stimulator of platelet aggregation. Platelets remain impaired for their life span (5 to 7 days) after exposure to aspirin. Aspirin also inhibits prostacyclin (PGI_2) activity in the smooth muscle of vascular walls. PGI_2 inhibits platelet aggregation, and the vascular endothelium can synthesize prostacyclin such that the platelet antiaggregating effect is maintained. The suppression of PGI_2 production by aspirin has been found to be dose and duration related; the higher the dose, the longer the cyclooxygenase production is suppressed. Therefore, the lower the aspirin dose, the less effect on PGI_2.[7] The optimal dose of aspirin should be the dose that inhibits TXA_2 with the least amount of PGI_2 inhibition. It has been shown that an aspirin dose of 325 mg/day will inhibit TXA_2 but will not significantly inhibit PGI_2 production. There is probably a point at which lower doses of aspirin do not completely block TXA_2, and recent studies indicate that the lowest effective dose may be in the range of 50 mg/day.[59] Upper GI discomfort and bleeding are the most common adverse effects of aspirin and have been shown to be dose related. The highest rates of GI bleeding (5%) have been reported in patients receiving 1,200 mg/day as compared with rates of 2% in patients taking the more commonly prescribed 300 mg/day. Upper GI symptoms are much more common than frank bleeding, however, with 40% of patients affected at 1,200 mg/day and 25% at 300 mg/day.[60] In the ESPS-2 study, even 50 mg/day of aspirin was associated with a twofold increase in bleeding over the placebo group.[32]

Low doses (<100 mg) of aspirin quickly inhibit cyclooxygenase in all the platelets in the circulation. Therefore, the onset of the antiplatelet effect of aspirin is less than 60 minutes.[61] It has been reported, however, that some patients either have or develop "aspirin resistance" and can require higher doses to achieve the desired antiplatelet effect.[62] Despite this, routine testing for aspirin resistance is not recommended. It was observed recently that administration of ibuprofen prior to the administration of a daily aspirin dose inhibits the aspirin from binding irreversibly to the cyclooxygenase and can decrease its antiplatelet effect.[63] Current recommendations are to administer aspirin at least 2 hours before ibuprofen or to wait at least 4 hours after an ibuprofen dose.

Aspirin also has an antiinflammatory effect as it reduces levels of C-reactive protein (CRP), and this may partially explain its mechanism of action at reducing vascular events.[64]

Extended-Release Dipyridamole Plus Aspirin

Early studies of the role of dipyridamole in stroke prevention failed to show a benefit over that realized by aspirin alone. Dipyridamole in high doses is thought to inhibit platelet aggregation by inhibiting phosphodiesterase, leading to accumulation of cyclic adenosine monophosphate (cAMP) and cyclic guanosine monophosphate (cGMP) intracellularly, which prevent platelet activation. In addition, dipyridamole also enhances the antithrombotic potential of the vascular wall.[65] The ESPS-2 demonstrated the efficacy of high-dose ERDP alone and in combination with aspirin in secondary stroke prevention.[32] The extended-release formulation of dipyridamole is important in that it allows twice-daily administration and higher doses to be tolerated in patients. The use of immediate-release generic dipyridamole in combination with regular aspirin, in order to reduce costs, is unproven and should be discouraged.

In the ESPS-2, 25% of the patients who received combination dipyridamole and aspirin discontinued the therapy early, and the rate of discontinuation owing to headache was more than three times as common (10%) as in the aspirin-alone group (3%).[32] Even when patients were carefully educated and coached in the PRoFESS trial, discontinuation due to headache was six times higher in the ERDP-aspirin group (5.9% vs. 0.9%).[34] The headache caused by ERDP-ASA is mostly self-limiting and decreases after several days.[66]

Clopidogrel

Clopidogrel has a unique platelet antiaggregatory effect in that it is an inhibitor of the adenosine diphosphate (ADP) pathway of platelet aggregation and inhibits known stimuli to platelet aggregation.[7,31] This effect causes an alteration of the platelet membrane and interference with the membrane–fibrinogenic interaction leading to a blocking of the platelet glycoprotein IIb/IIIa receptor. A time lag of 3 to 7 days before the antiplatelet effect is maximal should be expected. The tolerability of clopidogrel 75 mg/day is at least as good as medium-dose (325 mg/day) aspirin, and there is less GI bleeding.[31] Clopidogrel is associated with an increased risk of diarrhea and rash, but discontinuation rates owing to adverse effects are similar to those with aspirin 325 mg/day (5.3% to 6%, respectively).[31] There is no excess neutropenia in patients taking clopidogrel, and rates of thrombotic thrombocytopenic purpura probably are no greater than background rates.[67]

Clopidogrel is a thienopyridine prodrug and needs to be biotransformed by the liver to an active metabolite. Evidence suggests that the antiplatelet effects of clopidogrel can be diminished in patients with reduced function CYP2C19[68] or in those receiving agents that inhibit hepatic metabolism.[69] Although high doses of the lipophilic statins atorvastatin and simvastatin can diminish the effectiveness of clopidogrel to inhibit platelet aggregation in vitro, there does not appear to be any adverse effect on atherothrombotic event rates.[70] In contrast, in a retrospective analysis of 8,205 patients, concomitant proton pump inhibitor and clopidogrel treatment was associated with increased adverse vascular outcomes after acute coronary syndromes.[69] Careful consideration should be given to using clopidogrel in patients with reduced ability to biotransform the agent to its active metabolite.

INVESTIGATIONAL STRATEGIES

Reperfusion

Various investigations aimed at opening the occluded cerebral artery and preserving its patency are under way in acute ischemic stroke patients.[71] Strategies being tried include longer-acting fibrinolytic agents, intraarterial fibrinolysis with t-PA and other agents, and endovascular clot removal using mechanical and laser-guided approaches. In addition, investigators are trying to identify, using sensitive MRI techniques, which patients benefit from reperfusion at time points outside the approved time window. Undoubtedly, efforts to reperfuse the ischemic brain will continue to be explored, so more patients will be eligible for this therapy.

Neuroprotection and Neurorestoration

Although many different neuroprotective agents have been studied in clinical trials of acute ischemic stroke, most have been unsuccessful.[72] Some of the most promising are agents with multiple proposed mechanisms of protection (e.g., albumin infusions, and minocycline).[72] In addition, hope exists that clinicians will be able to enhance the reparative process of the brain (neurorestoration) through targeted neurorehabilitation, membrane stabilization (citicoline),[73] and the use of neural and cell transplantation.[74]

A promising nonpharmacologic strategy that has been shown to provide neuroprotection in patients has been hypothermia.[72]

Clinical trials are under way to optimize the mechanism of cooling the ischemic brain (intravascular coils vs. surface cooling) and rewarming the patient after hypothermia.

HEMORRHAGIC STROKE

There are currently no standard pharmacologic strategies for treating intracerebral hemorrhage (ICH).[6] Medical guidelines for the management of blood pressure, raised intracranial pressure, and other medical complications of ICH are those required for the management of any acutely ill patient in a neurointensive care unit.[15] When ICH occurs in a patient on warfarin (INR >1.3), rapid reversal of anticoagulation to prevent expansion and allow surgical intervention is recommended. The methods recommended to achieve reversal include intravenous vitamin K, fresh frozen plasma (FFP), and hemostatic agents (factor VIIa and prothrombin-complex concentrate (PCC).[15,75] The optimal approach is yet to be determined.

Subarachnoid hemorrhage (SAH) owing to aneurysm rupture is associated with a high incidence of delayed cerebral ischemia (DCI) in the 2 weeks following the bleeding episode. Vasospasm of the cerebral vasculature is thought to be responsible for DCI and occurs between 4 and 21 days after the bleed, peaking at days 5 through 9.[23] The calcium channel blocker nimodipine (60 mg every 4 hours for 21 days), along with maintenance of intravascular volume with pressor therapy, is recommended to reduce the incidence and severity of neurologic deficits owing to DCI.[23]

PHARMACOECONOMIC CONSIDERATIONS

Although t-PA is expensive, when the total healthcare costs are factored in, savings can accrue to the healthcare system as a direct result of appropriate t-PA therapy.[76] It has been estimated that, at a rate of $600 per patient treated, annual cost savings of $15 and $22 million could be realized by increasing national t-PA use to 4% and 6%, respectively (from the current 2%).[77]

In antithrombotic prophylaxis for atrial fibrillation, warfarin therapy was evaluated using quality-adjusted life-years (QALYs) saved.[78] It was found that in patients with atrial fibrillation and one additional risk factor, warfarin therapy cost $8,000 per QALY saved. In higher-risk patients, those with atrial fibrillation and two or more risk factors, warfarin use is cost saving. The cost-effectiveness of the various other secondary prevention strategies have been determined as well.[79,80] Without a doubt, aspirin, owing to its extremely low acquisition cost (pennies daily), is cost saving. In other words, it reduces costs at the same time as saving QALYs. The use of clopidogrel or ERDP-ASA is associated with higher efficacy but significantly greater costs as well (up to $3 daily). In fact ERDP-ASA was associated with $5,000 to $15,000 per QALY (adjusted for the acquisition cost) and clopidogrel was $26,580 per QALY. In addition, high-dose atorvastatin, as administered to stroke patients in the SPARCL trial, was estimated to result in an additional cost of $6,500 to $21,000 per QALY gained.[80] Any cost per QALY less than $50,000 is thought to be "cost-effective."[79] These estimates are extremely dependent on the assumptions made in the model. Cost-effectiveness in an individual patient is much more difficult to discern.

Primary prevention strategies that address the risk factors for ischemic stroke can be powerful in reducing the costs of stroke. Many of the stroke risk factors can be modified and some eliminated at very low costs (lifestyle changes), therefore developing risk-factor-reduction strategies can be the most cost-effective measure of all. More research is needed in identifying the cost-effectiveness of other forms of acute stroke treatment.

CLINICAL CONTROVERSIES

The use of full-dose unfractionated heparin in the management of acute ischemic stroke remains controversial despite years of debate and a lack of evidence supporting its use. Proponents of the therapy cite strong anecdotal evidence of positive responses in selected patients who have never been studied in clinical trials.

The use of intracranial angioplasty and stenting is strongly supported in the few institutions where the technology exists. Whether these procedures should be attempted in patients outside clinical trials remains controversial.

The use of surgical evacuation of intracranial hemorrhage with and without instillation of fibrinolytic agents is controversial. Although fervently pursued in select centers and countries, indications and outcomes are not known. Results of ongoing clinical trials can assist in settling this controversy.

EVALUATION OF THERAPEUTIC OUTCOMES

MONITORING OF THE PHARMACEUTICAL CARE PLAN

Patients with acute stroke should be monitored intensely for the development of neurologic worsening (recurrence or extension), complications (thromboembolism or infection), or adverse effects from pharmacologic or nonpharmacologic interventions. The most common reasons for deterioration in a stroke patient are (a) extension of the original lesion—ischemic or hemorrhagic—in the brain, (b) development of cerebral edema and raised intracranial pressure, (c) hypertensive emergency, (d) infection (urinary and respiratory most common), (e) venous thromboembolism (DVT and pulmonary embolism), (f) electrolyte abnormalities and cardiac rhythm disturbances (can be associated with brain injury), and (g) recurrent stroke.

The approach to monitoring the stroke patient is summarized in Table 27–5. The plan should be customized for individual patients based on their comorbidities and ongoing disease processes.

ABBREVIATIONS

ACE: angiotensin-converting enzyme
AMI: acute myocardial infarction
ADP: adenosine diphosphate
AHA: American Heart Association
ARB: angiotensin II receptor blocker
ATP: adenosine triphosphate
AVM: arteriovenous malformation
cAMP: cyclic adenosine monophosphate
CD: carotid Doppler
cGMP: cyclic guanosine monophosphate
CRP: C-reactive protein
CT scan: computed tomographic scan
CYP2C19: cytochrome P450 2C19
DCI: delayed cerebral ischemia
DVT: deep vein thrombosis
DWI: diffusion-weighted imaging

TABLE 27-5 Monitoring the Hospitalized Acute Stroke Patient

	Treatment	Parameter(s)	Frequency	Comments
Ischemic stroke	t-PA	BP, neurologic function, bleeding	Every 15 minutes × 1 hour; every 0.5 h × 6 h; every 1 h × 17 h; every shift after	
	Aspirin	Bleeding	Daily	
	Clopidogrel	Bleeding	Daily	
	ERDP-ASA	Headache, bleeding	Daily	Headache usually transient (2–3 days) and may respond to simple analgesics
	Warfarin	Bleeding, INR, Hb/Hct	INR daily × 3 days; weekly until stable; monthly	
Hemorrhagic stroke		BP, neurologic function, ICP	Every 2 hours in ICU	Many patients require intervention with short-acting agents to reduce BP to <180 mm Hg systolic
All	Nimodipine (for SAH)	BP, neurologic function, fluid status	Every 2 hours in ICU	For infectious complications such as UTI or pneumonia
		Temperature, CBC	Temp. every 8 hours; CBC daily	
		Pain (calf or chest)	Every 8 hours	For DVT, MI, acute headache
		Electrolytes and ECG	Up to daily	For fluid and electrolyte imbalances, cardiac rhythm abnormalities
	Heparins for DVT prophylaxis	Bleeding, platelets	Bleeding daily, platelets if suspected thrombocytopenia	

BP, blood pressure; CBC, complete blood count; DVT, deep-vein thrombosis; ECG, electrocardiography, ERDP-ASA, extended-release dipyridamole plus aspirin; Hb/Hct, hemoglobin/hematocrit; ICP, intracranial pressure; ICU, intensive care unit; MI, myocardial infarction; SAH, subarachnoid hemorrhage.

ECG: electrocardiogram

ERDP: extended-release dipyridamole

ESPRIT: European/Australasian Stroke Prevention in Reversible Ischemia Trial

ESPS-2: European Stroke Prevention Study 2

EVD: external ventricular drainage

FFP: fresh frozen plasma

GI: gastrointestinal

ICH: intracerebral hemorrhage

INR: international normalized ratio

JNC: Joint National Committee

LDL: low-density lipoprotein

MI: myocardial infarction

MRI: magnetic resonance imaging

NCEP: National Cholesterol Education Program

NIHSS: National Institutes of Health Stroke Scale

NINDS: National Institute of Neurologic Disorders and Stroke

NVAF: nonvalvular atrial fibrillation

PAD: peripheral arterial disease

PCC: prothrombin-complex concentrate

PGI_2: prostacyclin

PRoFESS: Prevention Regimen for Effectively Avoiding Second Strokes

QALY: quality-adjusted life-year

RRR: relative risk reduction

SAH: subarachnoid hemorrhage

TCD: transcranial Doppler

TEE: transesophageal echocardiography

TIA: transient ischemic attack

TTE: transthoracic echocardiography

TXA_2: thromboxane A_2

t-PA: tissue plasminogen activator

CHAPTER 28

Dyslipidemia

ROBERT L. TALBERT

KEY CONCEPTS

1. Hypercholesterolemia, elevated low-density lipoprotein (LDL), and low high-density lipoprotein (HDL) are unequivocally linked to increased risk for coronary heart disease and cerebrovascular morbidity and mortality; LDL is the primary target.
2. Multiple genetic abnormalities and environmental factors are involved in clinical lipid abnormalities and routinely used clinical laboratory measurements do not define the underlying abnormalities.
3. Initial therapy for any lipoprotein disorder is therapeutic lifestyle changes with restricted intake of total and saturated fat and cholesterol and a modest increase in polyunsaturated fat intake, along with a program of regular exercise and weight reduction, if needed.
4. If pharmacologic therapy is insufficient after therapeutic lifestyle changes, lipid-lowering agents should be chosen based on the specific lipoprotein disorder presentation and the severity of the lipid abnormality.
5. Considering compliance, adverse effects, and effectiveness, statins are the drugs of choice for patients with hypercholesterolemia because they are the most potent form of monotherapy and are cost effective in patients with known CAD or multiple risk factors and in high risk primary prevention patients.
6. Patients not responding to statin monotherapy may be treated with combination therapy for hypercholesterolemia, but should be monitored closely because of an increased risk for adverse effects and drug interactions.
7. Hypertriglyceridemia usually responds well to niacin, gemfibrozil, and fenofibrate; high dose niacin should be used cautiously in diabetics because of worsening glycemic control. Statins lower triglycerides to a variable extent, depending on baseline triglyceride concentration and statin potency.
8. Low HDL-C is addressed with lifestyle modifications such as smoking cessation and increased exercise; niacin and gemfibrozil and fenofibrate can significantly increase HDL-C as well.
9. Reductions in elevated total cholesterol and LDL-C reduce CHD mortality and total mortality; increasing HDL reduces CHD events as well. Aggressive treatment of hypercholesterolemia results in fewer patients progressing to myocardial infarction, angina, and stroke, and reduces the need for interventions such as coronary artery bypass graft and percutaneous transluminal coronary angioplasty.
10. Lipid-lowering therapy is generally considered to be cost effective, particularly in secondary intervention and high risk patients.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

Cholesterol, triglycerides, and phospholipids are the major lipids in the body and they are transported as complexes of lipids and proteins known as lipoproteins. Plasma lipoproteins are spherical particles with surfaces that consist largely of phospholipid, free cholesterol, and protein, and cores that consist mostly of triglyceride and cholesterol ester (Fig. 28–1). The three major classes of lipoproteins found in serum are low density lipoproteins (LDL), high density lipoproteins (HDL), and very low density lipoproteins (VLDL). VLDL is carried in the circulation as triglyceride and VLDL can be estimated by dividing the triglyceride concentration by five if the triglyceride concentration is below 250 mg/dL. Intermediate density lipoprotein resides between VLDL and LDL and is included in the LDL measurement in routine clinical measurement. Abnormalities of plasma lipoproteins can result in a predisposition to coronary, cerebrovascular, and peripheral vascular arterial disease and constitutes one of the major risk factors for coronary heart disease (CHD). Accumulating evidence over the last decades had linked elevated total and LDL cholesterol and reduced HDL to the development of CHD. Premature coronary atherosclerosis, leading to the manifestations of ischemic heart disease (see Chapter 23), is the most common and significant consequence of dyslipidemia. The National Cholesterol Education Program (NCEP) Adult Treatment Panel III (ATP III) published its third report summarizing these data and giving recommendations for the management of hypercholesterolemia in adults.[1,2] This report and the later update modify earlier recommendations and provide a new way of risk-stratifying patients based on multiple risk factors, the presence of diabetes, and the metabolic syndrome. The American Heart Association (AHA) also provides guidelines for primary and secondary prevention of CHD.[3,45]

Total cholesterol and LDL-C increase throughout life in men and women, representing an atherogenic pattern characteristic of Westernized society diets.[6] Based on estimates from the American Heart Association (AHA), 46.8% or 10.2 million American adults over age 20 years have total cholesterol levels of 200 mg/dL or higher.[7] More than half of individuals at borderline-high risk remain unaware that they have hypercholesterolemia and fewer than half of highest risk persons (those with symptomatic CHD) are receiving

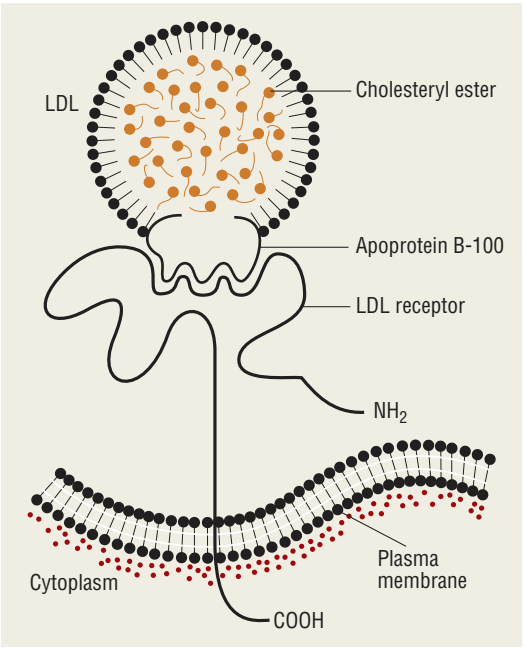

FIGURE 28-1. Diagrammatic representation of the structure of low-density lipoprotein (LDL), the LDL receptor, and the binding of LDL to the receptor via apolipoprotein B-100. *(From Ganong WF. Review of Medical Physiology, 22nd ed. New York: McGraw-Hill, 2005:303.)*

lipid-lowering treatment. About one-third of treated patients are achieving their LDL goal; fewer than 20% of CHD patients are at their LDL goal.[8,9] Changes in the NCEP guidelines have increased the number of persons eligible for therapeutic lifestyle changes (TLC) or lipid-lowering therapy by millions. NCEP estimates that only 26% of patients have an optimal LDL-C (<100 mg/dL) and that large numbers of patients are either untreated or under-treated.[1] Unfortunately, those patients at highest risk are less likely to be treated to desirable levels of LDL.[10] Although these numbers seem staggering in their enormity, substantial progress has been made, and the number of Americans with a desirable blood cholesterol level (<200 mg/dL) has risen to 49% from 45% from the earlier survey (1976 to 1980), while the average total cholesterol in this country has fallen from 220 mg/dL in 1960 to 1962, to 203 mg/dL in 2002.[11] Patients who are at risk but who have not yet experienced their first cardiovascular or cerebrovascular event [e.g., myocardial infarction (MI)] are termed primary prevention; whereas those with manifest vascular disease are termed secondary intervention.

1 Data from the Framingham and other studies demonstrate that the risk for developing cardiovascular disease is related to the degree of total cholesterol and LDL elevation in a graded, continuous fashion.[12] Hypercholesterolemia is additive to the other non-lipid risk factors for CHD, including cigarette smoking, hypertension, diabetes, low HDL levels, and electrocardiographic abnormalities. The presence of established CHD or prior MI increases the risk of MI five to seven times that seen in men or women without CHD, and LDL is a significant predictor of subsequent morbidity and mortality. About 50% of all MIs and at least 70% of CHD deaths occur in patients with known CHD, and these patients should therefore be a target for screening, identification, and treatment. Unfortunately, the identification of patients at high risk because of hypercholesterolemia or other lipid disorders is too frequently overlooked, because blood lipid levels are not always evaluated in this population, even after an event such as MI.

A comparison of the United States to other countries shows similar relationships between total cholesterol, LDL, and an inverse relationship with HDL to coronary artery disease (CAD) mortality.[12] On a positive note, the U.S. mortality rate is midway among the countries studied, and this country has had the greatest decline in CAD mortality (35% to 40%) in men and women over the last 10 years as compared to other countries. A decline in the prevalence of hypercholesterolemia in certain segments of the U.S. population parallels these trends in mortality.[1] LDL and the ratio of LDL to HDL have also been used to assess risk, but their use adds little information to total cholesterol alone, unless HDL is abnormally high or low. McQueen, et al., found that the ratio of apolipoprotein (Apo) B to ApoA1 was more predictive and consistent across gender and ethnic groups.[13] HDL transports cholesterol from lipid-laden foam cells to the liver. HDL has been shown to be protective for the occurrence of CHD, and an inverse relationship exists between CHD and HDL levels.[14]

VLDL, the major lipoprotein associated with triglycerides, is enriched with cholesterol esters, is smaller, denser, and more atherogenic than less-dense VLDL. Routine measurement of triglycerides cannot distinguish between the types of VLDL present in plasma. Elevation of triglyceride-rich lipoproteins is associated with low HDL, and this ratio predicts increased risk. The eight-year follow-up of the Copenhagen male study found a clear gradient of risk of ischemic heart disease (IHD) with increasing triglyceride levels within each level of HDL cholesterol. When compared to the lowest tertile of triglyceride concentrations, the highest tertile had 2.2 relative risk for IHD and the relationship extended across all concentrations of HDL.[15] The Helsinki heart study shows that hypertriglyceridemia and low HDL are associated with obesity (body mass index [BMI] >26 kg/m^2), smoking, sedentary life-style, blood pressure of ≥140/90 mm Hg, and blood glucose above 4.4 mmol/L, and that the benefit of gemfibrozil (risk reduction 68%, $P < 0.03$) was largely confined to overweight subjects.[16] Hypertriglyceridemia in certain instances—for example, diabetes mellitus, nephrotic syndrome, and chronic renal disease, and perhaps in women—is associated with increased cardiovascular risk. This is thought to be a consequence of the presence of atherogenic lipoproteins and of hypertriglyceridemia being a marker for them, as triglycerides are usually not independently predictive for CHD.[17]

LIPOPROTEIN METABOLISM AND TRANSPORT

Cholesterol and triglycerides, as the major plasma lipids, are essential substrates for cell membrane formation and hormone synthesis, and provide a source of free fatty acids.[18] Dyslipidemia may be defined as an elevation of total cholesterol, elevation in LDL cholesterol, elevation in triglycerides or low HDL cholesterol concentration, or some combination of these abnormalities. Lipids, being water immiscible, are not present in free form in the plasma, but rather circulate as lipoproteins. *Hyperlipoproteinemia* describes an increased concentration of the lipoprotein macromolecules that transport lipids in the plasma. The density of plasma lipoproteins is determined by their relative content of protein and lipid. Density, composition, size, and electrophoretic mobility divide lipoproteins into four classes (Table 28–1).

LDL has been further divided into LDL_1, or intermediate-density lipoprotein (density 1.006–1.019 g/mL), and LDL_2 (1.019–1.063 g/mL). LDL_2 is the major LDL component in plasma and it carries 60% to 70% of the total serum cholesterol. HDL has been subfractionated into HDL_2 (density 1.063–1.125 g/mL) and HDL_3 (1.125–1.21 g/mL). Fluctuations in HDL are usually caused by alterations in the levels of HDL_2. HDL normally carries about 20% to 30% of the total cholesterol. VLDL has also been subdivided

TABLE 28-1 Composition of Lipoprotein Isolated from Normal Subjects

			Composition (Weight %)				
					Cholesterol		
Lipoprotein Class[a]	**Density Range (g/mL)**	**Diameter (nm)**	**Protein**	**Triglyceride**	**Free**	**Ester**	**Phospholipid**
Chylomicrons	<0.94	75–1200	1–2	80–95	1–3	2–4	3–9
VLDL	0.94–1.006	30–80	6–10	55–80	4–8	16–22	10–20
LDL	1.006–1.063	18–25	18–22	5–15	6–8	45–50	18–24
HDL	1.063–1.21	5–12	45–55	5–10	3–5	15–20	20–30

[a]VLDL denotes very-low-density lipoprotein, LDL low-density lipoprotein, and HDL high-density lipoprotein.

into three classes, and it carries about 10% to 15% of serum cholesterol and most of the triglyceride in the fasting state. VLDL is the precursor for LDL, and VLDL remnants may also be atherogenic. Table 28–2 shows the characteristics of the protein constituent of lipoproteins known as apolipoproteins. The structure of LDL, the LDL receptor, and the binding of the LDL to the receptor via apolipoprotein (Apo) B-100 is shown in Figure 28–1.

Chylomicrons, large triglyceride-rich particles containing apolipoprotein B-48, B-100, and E, are formed from dietary fat solubilized by bile salts in intestinal mucosal cells. Chylomicrons are normally not present in the plasma after a fast of 12 to 14 hours and are catabolized by lipoprotein lipase (LPL), which is activated by apolipoprotein C-II and in the vascular endothelium and hepatic lipase to form chylomicron remnants. The remnants that contain apolipoprotein E (Fig. 28–2) are taken up by the "remnant receptor," which may be an LDL receptor-related protein in the liver. Free cholesterol is liberated intracellularly after attachment to the remnant receptor. Chylomicrons also function to deliver dietary triglyceride to skeletal muscle and adipose tissue. During the catabolism of nascent chylomicrons to remnants, triglyceride is converted to free fatty acids and apolipoproteins A-I, A-II, A-IV (free in plasma), C-I, C-II, and C-III, and phospholipids are transferred to HDL. Apolipoprotein E and apolipoprotein C-II are transferred to chylomicrons from HDL and eventually back through these metabolic events. Hepatic VLDL synthesis is regulated in part by diet and hormones, and is inhibited by uptake of chylomicron remnants in the liver. VLDL is secreted from the liver and serially converted via LPL to intermediate-density lipoprotein (IDL), and finally, to LDL. VLDL receptors are found in adipose tissue and muscle, and bear close homology to the structure of LDL receptors.

LDL, the major cholesterol transport lipoprotein and having virtually only apolipoprotein B-100, is mostly derived from VLDL catabolism and cellular synthesis. When fasting and on low-fat intake in normal subjects, most cholesterol is synthesized and used in the extrahepatic organs, while most of the cholesterol carried by LDL is taken up by the liver for catabolism. In patients with homozygous familial hypercholesterolemia, enhanced synthesis of LDL may occur, because LDL clearance is reduced as a consequence of the lack of LDL receptors. LDL is catabolized through interaction of cell surface receptors found on liver, adrenal, and peripheral cells (including fibroblasts and smooth muscle cells). These cells recognize apolipoprotein B-100 on LDL, and after binding to a receptor on the cell membrane, LDL is internalized and degraded. In the normal fasting state, approximately 70% of LDL is cleared through a receptor-dependent mechanism, although this is highly dependent on the availability and type of saturated and mono- or polyunsaturated fat from dietary sources. Ingestion of cholesterol and saturated fatty acids such as C12:0, C14:0, and C16:0 are associated with reduction in LDL receptor activity, increased LDL production rate, and elevation in LDL plasma concentration. Receptor-independent mechanisms are

TABLE 28-2 Characteristics and Functions of Apolipoproteins

Apolipoprotein	**Lipoprotein Density Class**	**Approximate Plasma Concentration (mg/dL)**	**Approximate Molecular Weight (kd)**	**Reported Functions**	**Major Site of Synthesis**
A-I	Chylomicrons, HDL	120	28	Cofactor with LCAT, structural protein on HDL, ligand for HDL receptor	Liver, intestine
A-II	Chylomicrons, HDL	35	17	Structural protein for HDL, ligand for HDL receptor	Liver
A-IV	Chylomicrons, 1.21B	15	46	Possibly facilitates transfer of other apos between HDL and chylomicrons	Intestine
ApoLp(a)	LDL, HDL	10	500±	Bound to B-100, high homology with plasminogen, may prevent LDL uptake by B, E receptor	Liver
B-100	VLDL, LDL, IDL	100	540	Necessary for assembly and secretion of VLDL from the liver, structural protein of VLDL, IDL, LDL, ligand for LDL receptor	Liver
B-48	Chylomicrons	Trace	264	Necessary for assembly and secretion of chylomicrons from the small intestine	Intestine
C-I	Chylomicrons, VLDL, HDL	7	6.6	Cofactor with LCAT; may inhibit hepatic uptake of chylomicron and VLDL remnants	Liver
C-II	Chylomicrons, VLDL, HDL	4	8.9	Activator of LPL	Liver
C-III	Chylomicrons, VLDL, HDL	13	8.8	Inhibitor with LPL; may inhibit hepatic uptake of chylomicron and VLDL remnants	Liver
D	HDL	6	32	?	?
E2-E4	Chylomicrons, VLDL, HDL	5	34	Ligand for several lipoproteins to LDL receptor, LRP and possibly to a separate hepatic apo E receptor	Liver

LCAT, lecithin-cholesterol acyltransferase; HL, hepatic lipase; IDL, intermediate density lipoprotein; LRP, LDL receptor-related protein. Other abbreviations are in Table 28–1.

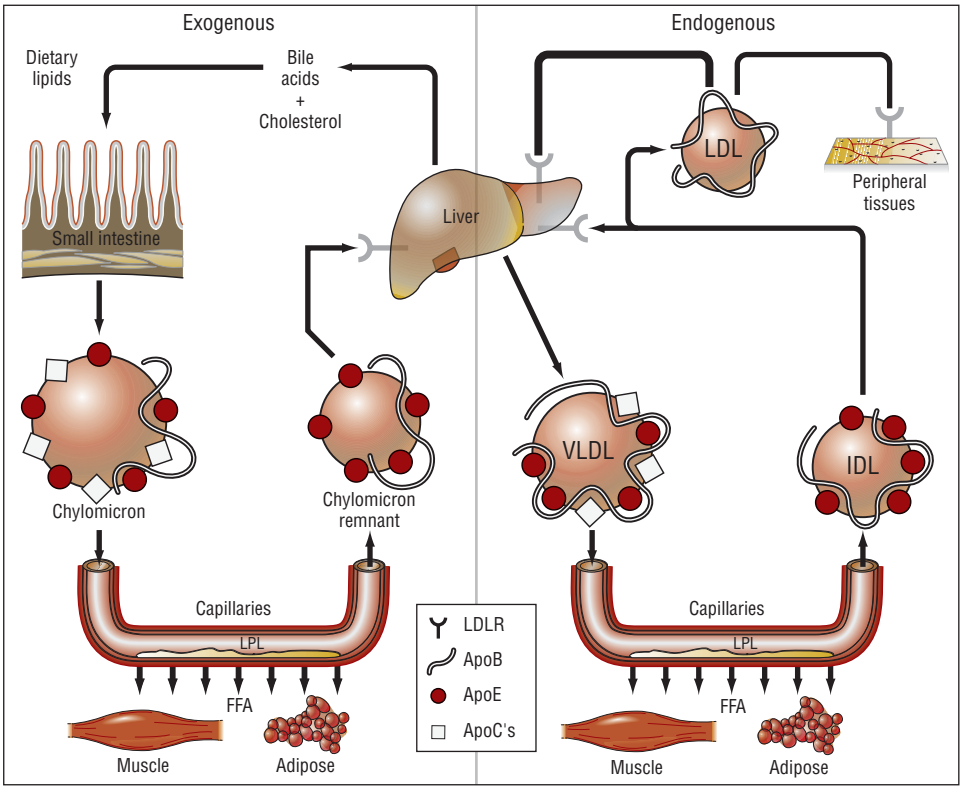

FIGURE 28-2. Simplified diagram of lipoprotein systems for transporting lipids in humans. In the exogenous system, chylomicrons rich in triglycerides of dietary origin are converted to chylomicron remnants rich in cholesteryl esters by the action of lipoprotein lipase (LPL). In the endogenous system, very-low-density lipoproteins (VLDL) rich in triglycerides are secreted by the liver and converted to intermediate-density lipoproteins (LDL) and then to low-density lipoproteins (LDL) rich in cholesteryl esters. Some of the LDLs enter the subendothelial space of arteries, are oxidized, and then are taken up by macrophages, wchich become foam cells. The letters on the chylomicrons, chylomicron remnants, VLDL, IDL, and LDL identify the primary apoproteins (ApoB, ApoC, ApoE) found in them. (LDLR, low-density lipoprotein receptor.) *(From Kasper DL, Braunwald E, Fauci AS, et al., eds. Harrison's Principles of Internal Medicine, 16th ed. New York, McGrawHill, 2005, p. 2289.)*

also involved to a lesser extent in the catabolism of LDL, and these receptors are present in many tissues, but are most active in animals in the adrenals and ovary. Increased intracellular cholesterol resulting from LDL catabolism inhibits the activity of 3-hydroxy-3-methylglutaryl coenzyme A reductase (HMG-CoA reductase), the rate-limiting enzyme for intracellular cholesterol biosynthesis (Fig. 28–3). Additional consequences of increased intracellular cholesterol include reduced synthesis of LDL receptors, which limits subsequent cholesterol uptake from the plasma, and accelerated activity of acyl coenzyme-A:cholesterol acyltransferase to facilitate cholesterol storage within cells. LDL cholesterol may also be excreted into bile and become part of the enterohepatic pool or may be lost in the stool. Lp(a) is a cholesterol-rich lipoprotein similar to LDL in composition and density and with close homology to fibrinogen. It is reported to be an important independent risk factor for the development of premature cardiovascular disease.

Nascent HDL is derived from liver and gut synthesis, primarily in the form of apolipoprotein A-I phospholipid discs.[14] Esterification of free cholesterol in nascent HDL and from peripheral tissues to cholesteryl esters by lecithin-cholesterol acyltransferase (LCAT) results in the production of HDL_3. Further addition of tissue cholesterol to HDL_3 results in the formation of HDL_2. HDL_2 can also be formed from remodeling of chylomicrons and VLDL catabolism. HDL_2 may be converted back to HDL_3 by the action of hepatic lipase and by the transfer of cholesteryl esters to the liver, LDL, and VLDL. Apolipoprotein A-I production is increased by estrogens, leading to higher HDL levels in women and in individuals receiving estrogen. Transfer of excess cholesterol from peripheral tissues by HDL is called *reverse cholesterol transport.* Putative HDL receptors in peripheral cells facilitate the uptake of cholesterol by HDL, which transfers cholesterol to either VLDL and LDL, or to the liver for secretion into bile or conversion into bile acids. These processes serve to rid peripheral tissue (e.g., coronary arteries) of excessive amounts of cholesterol, and account for some of the protective effects noted with increasing HDL in women and other factors that elevate HDL levels. Variants of the cholesterol ester transfer protein (CETP) have been demonstrated in humans, and the B1B1 genotype is associated with lower HDL and progression of coronary atherosclerosis. Inhibition of CETP leads to elevations in HDL. Unfortunately, when CETP inhibitors have been tested in clinical trials, they did not induce regression of atherosclerotic plaque and were associated with higher blood pressure and CHD events.[19–21] The effect of CETP inhibition on blood pressure and HDL are disconcordant.[22]

The "response-to-injury" hypothesis states that risk factors such as oxidized LDL, mechanical injury to the endothelium (e.g., percutaneous transluminal angioplasty), excessive homocysteine, immunologic attack, or infection-induced (e.g., *Chlamydia,* herpes simplex virus-1) changes in endothelial and intimal function lead to endothelial dysfunction and a series of cellular interactions that culminate in atherosclerosis. *C-reactive protein* (CRP) is an acute phase reactant and a marker for inflammation; it may be useful in identifying patients at risk for developing CAD.[23] The eventual outcomes of this atherogenic cascade are clinical events such as angina, MI, arrhythmias, stroke, peripheral arterial disease, abdominal aortic aneurysm, and sudden death. Atherosclerotic lesions are thought to arise from transport and retention of plasma LDL-cholesterol through the endothelial cell layer into the extracellular matrix of the subendothelial space. Once in the artery wall, LDL is chemically modified through oxidation and non-enzymatic glycation. Mildly oxidized LDL then recruits monocytes into the artery wall, which become transformed into macrophages. Macrophages have tremendous potential for accelerating LDL oxidation and apolipoprotein B accumulation, and altering the receptor-mediated uptake of LDL into the artery wall from the usual LDL-receptor to a "scavenger receptor" not regulated by cell content of cholesterol. Oxidized LDL increases plasminogen inhibitor levels (promotion of coagulation), induces the expression of endothelin (vasoconstrictive substance), inhibits the expression of nitric oxide (a vasodilator and platelet inhibitor), and is toxic to macrophages if highly oxidized. As oxidation of biologically

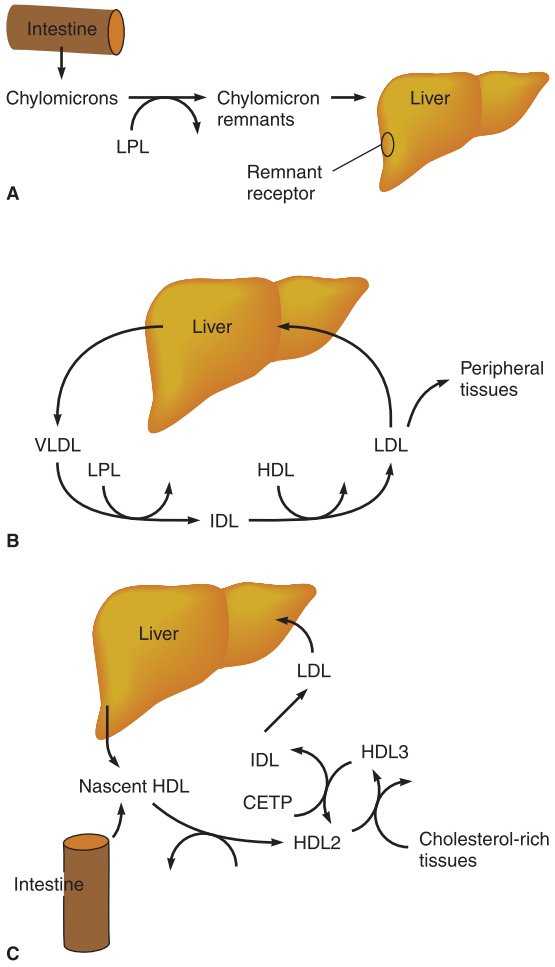

FIGURE 28-3. Biosynthetic pathway for cholesterol. The rate-limiting enzyme in this pathway is 3-hydroxy-3-methylglutaryl coenzyme A reductase (HMG-CoA reductase). (CETP, cholesterol ester transfer protein; HDL, high-density lipoprotein; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; LPL, lipoprotein lipase; VLDL, very-low-density lipoprotein.) *(Modified from Breslow JL. Genetic basis of lipoprotein disorders. J Clin Invest 1989;84:373.).* A. Exogenous pathway; B. Endogenous pathway; C. Reverse cholesterol transport.

active lipids proceeds, other lipids such as lysophosphatidylcholine, hydroperoxides, and aldehydic breakdown products of fatty acids and oxysterol are formed, which continue the reaction within the tissue. These events lead to a massive accumulation of cholesterol. The cholesterol-laden macrophages become foam cells; *foam cells* are the earliest recognized cells of the arterial fatty streak.

Oxidized LDL provokes an inflammatory response, which is mediated by a number of chemoattractants and cytokines. Examples of each that appear to be involved at different stages of lesion development include monocyte chemoattractant protein 1 (MCP-1); monocyte colony stimulating factor (M-CSF); *gro;* vascular cell adhesion molecule (VCAM-1); E-selectin (ELAM-1); intercellular adhesion molecule (ICAM-1); platelet-derived growth factor (PDGF); vascular endothelial growth factor (VEGF); transforming growth factors (TGFα and TGFβ); interleukin-1 and interleukin-6 (IL-1, IL-6); and the ratio of interleukin-10 and interleukin-12 (IL-10, IL-12). It appears that some of these factors (e.g., MCP-1 and M-CSF) participate early in the process of monocyte-macrophage attachment and transmigration across the endothelium, whereas others (PDGF and VCAM-1) promote later lesion growth.[24] The extent of oxidation and the inflammatory response is under genetic control of a major gene termed *Ath*-1 based on murine model studies. The process of aging may lead to lipoproteins that are more

TABLE 28-3 Fredrickson-Levy-Lees Classification of Hyperlipoproteinemia

Type	Lipoprotein Elevation
I	Chylomicrons
IIa	LDL
IIb	LDL + VLDL
III	IDL (LDL_1)
IV	VLDL
V	VLDL + Chylomicrons

LDL indicates low-density lipoprotein; VLDL indicates very low-density lipoprotien; IDL indicates intermediate-density lipoprotein.

susceptible to oxidation and have longer resident time in the vascular compartment. Two proteins associated with HDL—apolipoprotein J (apoJ) and paraxonase (PON) appear to play an important role in minimizing the oxidation of LDL-C.[25] Increased recognition of the role of these growth-regulatory molecules provides the possibility of future directions for antagonists to regulatory molecules such as PDGF, TGFβ, and the interleukins. Repeated injury and repair within an atherosclerotic plaque eventually leads to a fibrous cap protecting the underlying core of lipids, collagen, calcium, and inflammatory cells such as T-lymphocytes. Maintenance of the fibrous plaque is critical to prevent plaque rupture and subsequent coronary thrombosis.[26] An imbalance between plaque synthesis and degradation may lead to a weakened or vulnerable plaque prone to rupture. The fibrous cap may become weakened through decreased synthesis of the extracellular matrix or increased degradation of the matrix. The cytokine interferon-γ, produced by T-lymphocytes, inhibits the ability of smooth muscle cells to synthesize collagen, a structurally important component of the fibrous cap. A family of enzymes known as matrix metalloproteinases can degrade all major constituents of the vascular extracellular matrix: collagen, elastin, and proteoglycans.[27]

2 Lipoprotein disorders are classified into six categories, which are commonly used for phenotypical description of dyslipidemia (Table 28–3). Specific genetic defects with disrupted protein, cell, and organ function give rise to several disorders within each family of lipoproteins (Table 28–4). In other words, an elevated cholesterol level does not necessarily equate with familial hypercholesterolemia or type IIa, as cholesterol may also be elevated in other lipoprotein disorders and the lipoprotein pattern does not describe the underlying genetic defect. The preceding discussion has focused on primary or genetic dyslipoproteinemia. It should be remembered that secondary forms exist and that several drugs may also elevate lipid levels (Table 28–5). These secondary forms of hyperlipidemia should be initially managed by correcting the underlying abnormality, including modification of drug therapy when appropriate.

Familial hypercholesterolemia is characterized by (a) a selective elevation in the plasma level of LDL; (b) deposition of LDL-derived cholesterol in tendons (xanthomas) and arteries (atheromas); and (c) inheritance as an autosomal dominant trait with homozygotes more severely affected than heterozygotes. Homozygotes (prevalence 1 in 1,000,000) have severe hypercholesterolemia (650–1000 mg/dL), with the early appearance of cutaneous xanthomas and fatal CHD generally before the age of 20. The primary defect in familial hypercholesterolemia is the inability to bind LDL to the LDL receptor (LDL-R) or, rarely, a defect of internalizing the LDL-R complex into the cell after normal binding. Homozygotes have essentially no functional LDL receptors. This leads to lack of LDL degradation by cells and unregulated biosynthesis of cholesterol, with total cholesterol and LDL-C being inversely proportional to the deficit in LDL receptors. Heterozygotes have only about one-half of the normal

TABLE 28-4 Lipoprotein Disorders

Lipid Phenotype	Plasma Lipid Levels, mmol/L (mg/dL)L	Lipoproteins		Clinical Signs
		Elevated	Phenotype	
Isolated hypercholesterolemia				
Familial hypercholesterolemia	Heterozygotes TC = 7–13 (275–500)	LDL	IIa	Usually develops xanthomas in adulthood and vascular disease at 30–50 years
	Homozygotes TC >13 (>500)	LDL	IIa	Usually develops xanthomas in adulthood and vascular disease in childhood
Familial defective apo B100	Heterozygotes TC = 7–13 (275–500)	LDL	IIa	
Polygenic hypercholesterolemia	TC = 6.5–9 (250–350)	LDL	IIa	Usually asymptomatic until vascular disease develops; no xanthomas
Isolated hypertriglyceridemia				
Familial hypertriglyceridemia	TG = 2.8–8.5 (250–750)	VLDL	IV	Asymptomatic; may be associated with increased risk of vascular disease
Familial LPL deficiency	TG >8.5 (750)	Chylomicrons, VLDL	I, V	May be asymptomatic; may be associated with pancreatitits, abdominal pain, hepatosplenoggaly
Familial apo CII deficiency	TG >8.5 (>750)	Chylomicrons, VLDL	I, V	As above
Hypertriglyceridemia and hypercholesterolemia				
Combined hyperlipidemia	TG = 2.8–8.5 (250–750); TC = 6.5–13 (250–500)	VLDL, LDL	IIb	Usually asymptomatic until vascular disease develops; familial form may also present as isolated high TG or an isolated high LDL cholesterol
Dysbetalipoproteinemia	TG = 2.8–8.5 (250–750); TC = 6.5–13 (250–500)	VLDL, IDL; LDL normal	III	Usually asymptomatic until vascular disease develops; may have palmar or tuboeruptive xanthomas

Abbreviations: TC, total cholesterol; TG, triglycerides, LPL, lipoprotein lipase. Other abbreviations as in Table 28–1.

TABLE 28-5 Secondary Causes of Lipoprotein Abnormalities

Hypercholesterolemia	Hypothyroidism
	Obstructive liver disease
	Nephrotic syndrome
	Anorexia nervosa
	Acute intermittent porphyria
	Drugs: Progestins, thiazide diuretics, glucocorticoids, β-blockers, isotretinoin, protease inhibitors, cyclosporine, mirtazapine, sirolimus
Hypertriglyceridemia	Obesity
	Diabetes mellitus
	Lipodystrophy
	Glycogen storage disease
	Ileal bypass surgery
	Sepsis
	Pregnancy
	Acute hepatitis
	Systemic lupus erythematous
	Monoclonal gammopathy: multiple myeloma, lymphoma
	Drugs: Alcohol, estrogens, isotretinoin, β-blockers, glucocorticoids, bile-acid resins, thiazides; asparaginase, interferons, azole antifungals, mirtazapine, anabolic steroids, sirolimus, bexarotene
Hypocholesterolemia	Malnutrition
	Malabsorption
	Myeloproliferative diseases
	Chronic infectious diseases: AIDS, tuberculosis
	Monoclonal gammopathy
	Chronic liver disease
Low HDL	Malnutrition
	Obesity
	Drugs: Non-ISA β-blockers, anabolic steroids, probucol, isotretinoin, progestins

number of LDL receptors, total cholesterol levels in the range of 300–600 mg/dL, and cardiovascular events beginning in the third and fourth decades of life.

Familial LPL deficiency is a rare, autosomal recessive trait characterized by a massive accumulation of chylomicrons and corresponding increase in plasma triglycerides or a type I lipoprotein pattern. VLDL concentration is normal. The presenting manifestations include repeated attacks of pancreatitis and abdominal pain, eruptive cutaneous xanthomatosis, and hepatosplenomegaly beginning in childhood. Symptom severity is proportional to dietary fat intake, and consequently to the elevation of chylomicrons. LPL is normally released from vascular endothelium or by heparin and hydrolyzes chylomicrons and VLDL (see Fig. 28–2). Diagnosis is based on low or absent enzyme activity with normal human plasma or apolipoprotein C-II, a cofactor of the enzyme. Accelerated atherosclerosis is not associated with this disease. Abdominal pain, pancreatitis, eruptive xanthomas, and peripheral polyneuropathy characterize type V (VLDL and chylomicrons). Symptoms may occur in childhood, but usually the disorder is expressed at a later age. The risk of atherosclerosis is increased with this disorder. These patients are commonly obese, hyperuricemic, and diabetic, and alcohol intake, exogenous estrogens, and renal insufficiency tend to be exacerbating factors.

Patients with familial type III hyperlipoproteinemia (also called dysbetalipoproteinemia, broad-band or β-VLDL) develop these clinical features after 20 years of age: xanthoma striata palmaris (yellow discolorations of the palmar and digital creases); tuberous or tuberoeruptive xanthomas (bulbous cutaneous xanthomas); and severe atherosclerosis involving the coronary arteries, internal carotids, and abdominal aorta. A defective structure of apolipoprotein E does not allow normal hepatic surface receptor binding of remnant particles derived from chylomicrons and VLDL (known

as IDL). Aggravating factors such as obesity, diabetes, or pregnancy may promote overproduction of apo-B-containing lipoproteins. Although homozygosity for the defective allele (E_2/E_2) is common (1 in 100), only 1 in 10,000 express the full-blown picture, and interaction with other genetic or environmental factors, or both, is needed to produce clinical disease.

Familial combined hyperlipidemia is characterized by elevations in total cholesterol, triglycerides, decreased HDL, increased apolipoprotein B and small, dense LDL.[28] It is associated with premature CHD and may be difficult to diagnose since the lipid levels do not consistently display the same pattern.

Type IV hyperlipoproteinemia is common and occurs in adulthood, primarily in patients who are obese, diabetic, and hyperuricemic and do not have xanthomas. It may be secondary to alcohol ingestion and can be aggravated by stress, progestins, oral contraceptives, thiazides, or β-blockers. Two genetic patterns occur in type IV hyperlipoproteinemia: familial hypertriglyceridemia, which does not carry a great risk for premature CAD, and familial combined hyperlipidemia, which is associated with increased risk of cardiovascular disease.

Rare forms of lipoprotein disorders may include hypobetalipoproteinemia, abetalipoproteinemia, Tangier disease, LCAT deficiency (fish-eye disease), cerebrotendinous xanthomatosis, and sitosterolemia. Most of these rare lipoprotein disorders do not result in premature atherosclerosis, with the exceptions of familial LCAT deficiency, cerebrotendinous xanthomatosis (CTX), and sitosterolemia with xanthomatosis. Their treatment consists of dietary restriction of plant sterols (sitosterolemia with xanthomatosis), chenodeoxycholic acid (CTX), or, potentially, blood transfusion (LCAT deficiency).

CLINICAL PRESENTATION

General

- Most patients are asymptomatic for many years prior to clinically evident disease.
- Patients with the metabolic syndrome may have three or more of the following: abdominal obesity, atherogenic dyslipidemia, raised blood pressure, insulin resistance ± glucose intolerance, prothrombotic state, or proinflammatory state.

Symptoms

- None to chest pain, palpitations, sweating, anxiety, shortness of breath, loss of consciousness or difficulty with speech or movement, abdominal pain, sudden death.

Signs

- None to abdominal pain, pancreatitis, eruptive xanthomas, peripheral polyneuropathy, high blood pressure, body mass index >30 kg/m^2 or waist size >40 inches in men (35 inches in women).

Laboratory Tests

- Elevations in total cholesterol, LDL, triglycerides, apolipoprotein B, C-reactive protein (CRP).
- Low HDL

Other Diagnostic Tests

- Lipoprotein (a), and small, dense LDL (pattern B), HDL subclassification, apolipoprotein E isoforms, apolipoprotein A-1, fibrinogen, folate, lipoprotein-associated phospholipase A_2.
- Various screening tests for manifestations of vascular disease (ankle-brachial index, exercise testing, magnetic resonance imaging) and diabetes (fasting glucose, oral glucose tolerance test, hemoglobin A_{1c}).

TABLE 28-6 Classification of Total-, LDL-, HDL-Cholesterol and Triglycerides

Total cholesterol	
<200 mg/dL	Desirable
200–239 mg/dL	Borderline high
≥240 mg/dL	High
LDL cholesterol	
<100 mg/dL	Optimal
100–129 mg/dL	Near or above optimal
130–159 mg/dL	Borderline high
160–189 mg/dL	High
≥190 mg/dL	Very high
HDL cholesterol	
<40 mg/dL	Low
≥60 mg/dL	High
Triglycerides	
<150 mg/dL	Normal
150–199 mg/dL	Borderline high
200–499 mg/dL	High
≥500 mg/dL	Very high

HDL indicates high-density lipoproteins
LDL indicates low-density lipoproteins

PATIENT EVALUATION

A fasting lipoprotein profile including total cholesterol, LDL-C, HDL-C, and triglycerides should be measured in all adults 20 years of age or older at least once every five years.[1] If the profile is obtained in the nonfasted state, only total cholesterol and HDL-C will be usable because LDL-C is usually a calculated value. If total cholesterol is ≥200 mg/dL, or if HDL-C is <40 mg/dL, a follow-up fasting lipoprotein profile should be obtained. After a lipid abnormality is confirmed (Table 28–6), major components of the evaluation are the history (including age, gender, and, if female, menstrual and hormone replacement status), physical examination, and laboratory investigations. A complete history and physical exam should assess (a) presence or absence of cardiovascular risk factors (Table 28–7) or definite cardiovascular disease in the individual; (b) family history of premature cardiovascular disease or lipid disorders; (c) presence or absence of secondary causes of lipid abnormalities, including concurrent medications (see Table 28–5); and (d) presence or absence of xanthomas or abdominal pain, or history of pancreatitis, renal or liver disease, peripheral vascular disease, abdominal aortic aneurysm, or cerebral vascular disease (carotid bruits, stroke, or transient ischemic attack). An important change in the ATP III guidelines is that diabetes mellitus is regarded

TABLE 28-7 Major Risk Factors (Exlusive of LDL Cholesterol) That Modify LDL Goals[a]

Age
  Men: ≥45 years
  Women: ≥55 years or premature menopause without estrogen replacement therapy
Family history of premature CHD (definite myocardial infarction or sudden death before 55 years of age in father or other male first-degree relative, or before 65 years of age in mother or other female first-degree relative)
Cigarette smoking
Hypertension (≥140/90 mm Hg or on antihypertensive medication)
Low HDL cholesterol (<40 mg/dL)[b]

[a]Diabetes is regarded as a coronary heart disease (CHD) risk equivalent, LDL indicates low-density lipoprotein, HDL indicates high-density lipoprotein.
[b]HDL cholesterol (≥60 mg/dL counts as a "negative" risk factor; its presence removes 1 risk factor from the total count).

TABLE 28-8 LDL Cholesterol Goals and Cutpoints for Therapeutic Lifestyle Changes (TLC) and Drug Therapy in Different Risk Categories[a]

Risk Category	LDL Goal (mg/dL)	LDL Level at Which to Initiate TLC (mg/dL)	LDL Level at Which to Consider Drug Therapy (mg/dL)
High risk: CHD or CHD risk equivalents (10-year risk >20%)	<100 mg/dL (optional goal: <70)	≥100	≥100 (<100 mg/dL; consider drug options)[b]
Moderately high risk: 2+ risk factors (10-year risk >10–20%)	<130	≥130	≥130 (100–129: consider drug options)
Moderate risk: 2+ risk factors (10-year risk <10%)	<130	≥130	≥160
Lower risk: 0–1 Risk factor[c]	<160	≥160	≥190 (160–189: LDL-lowering drug optional)

[a]LDL indicates low-density lipoprotein; CHD, coronary heart disease.

[b]Some authorities recommend use of LDL-lowering drugs in this category if an LDL cholesterol level of <100 mg/dL cannot be achieved by TLC. Others prefer use of drugs that primarily modify triglycerides and HDL, (e.g., nicotinic acid or fibrates). Clinical judgment also may call for deferring drug therapy in this subcategory.

[c]Almost all people with 0–1 risk factor have a 10-year risk <10%; thus, 10-year risk assessment in people with 0–1 risk factor is not necessary.

as a CHD risk equivalent.[1] The presence of diabetes in patients without known CHD is associated with the same level of risk as patients without diabetes but having confirmed CHD.[29,30] ATP III identifies four categories of risk that modify the goals and modalities of LDL-lowering therapy (Table 28–8).[2] The highest category is known CHD or CHD risk equivalents, which is defined as the risk for major coronary events equal to or greater than established CHD, that is, >20% per 10 years (2% per year). The next category is moderately high risk consisting of patients with multiple (2+) risk factors in which 10-year risk for CHD is 10–20%. Moderate risk is defined as ≥2 risk factors and a 10-year risk of ≤10%. The lowest risk category consists of persons with 0 to 1 risk factor. Risk is estimated from Framingham risk scores.[31] Risk is estimated based on the patient's age, LDL-C or total cholesterol level, blood pressure, the presence of diabetes, and smoking status (Table 28–7). This approach for a single patient is referred to as case finding or patient-based, whereas large-scale screening and recommendations for the general populace, health care providers, and the food industry are called a population-based approach.

Measurement of plasma cholesterol (which is about 3% lower than serum determinations), triglyceride, and HDL-C levels after a 12-hour or longer fast is important, as triglycerides may be elevated in nonfasted individuals. Total cholesterol is only modestly affected by fasting. Analytic and biologic variability can have a major impact on the measurement and interpretation of cholesterol (or any other laboratory test). Analytic variability can be minimized through the use of adequate quality control procedures, including internal training, routine calibration and monitoring, and external proficiency testing. Even with these measures, the coefficient of variability in the best procedures can acceptably be up to 5%, and when combined with average biologic variability, total variability may be as high as about 22%. Analytic variability with desktop equipment generally is greater in the fingerstick capillary blood methods, usually yielding measurements less than those from a clinical laboratory, and this technology should be considered for use only as a screening method. Reliance on desktop methods can result in misclassification of 7% to 14% of patients if capillary blood is used. Two determinations, one to eight weeks apart, with the patient on a stable diet and weight, and in the absence of acute illness, are recommended to minimize variability and to obtain a reliable baseline.[1] If the total cholesterol is greater than 200 mg/dL, a second determination is recommended, and if the values are more than 30 mg/dL apart, the average of three values should be used. Familiarity with the method and quality control procedures employed by local laboratories is essential for interpretation of reported values. If the physical examination and history are insufficient to diagnose a familial disorder, then agarose-gel lipoprotein electrophoresis is useful to determine which class of lipoproteins is affected. If the triglyceride levels are below 400 mg/dL and neither type III hyperlipidemia nor chylomicrons are detected by electrophoresis, then one can calculate VLDL and LDL concentrations: VLDL = triglyceride/5; LDL = total cholesterol − (VLDL + HDL).

Because total cholesterol is comprised of cholesterol derived from LDL, VLDL, and HDL, determination of HDL is useful when total plasma cholesterol is elevated. HDL may be elevated by moderate alcohol ingestion (less than two drinks per day), physical exercise, smoking cessation, weight loss, oral contraceptives, phenytoin, and terbutaline. Smoking, obesity, a sedentary lifestyle and drugs such as β-blockers lower HDL. Only exercise and smoking cessation could be recommended as interventions for low HDL concentrations. Niacin and gemfibrozil also increase HDL concentrations.

The range of lipid concentrations represents a population mean plus or minus two standard deviations and does not define the risk of disease. Reference values for plasma total, LDL, and HDL cholesterol concentrations for men and women, as well as various ethnic groups, are available from the NHANES III.[6] Cholesterol and triglycerides increase throughout life until about the fifth decade for men and the sixth decade for women. Past these ages, total cholesterol and LDL plateau and fall slightly. HDL tends to fall slightly with time and more rapidly after menopause in women. Institution of a population-based approach for cholesterol reduction should shift the entire curve to the left, and the potential reduction in cardiovascular mortality would be proportional to mean reductions at any cholesterol concentration.

Based on a careful review of the experimental pathologic, genetic, and epidemiologic evidence relating to the relationship between blood cholesterol levels and CHD, the adult treatment panel III of the NCEP recommends that a fasting lipoprotein profile and risk factor assessment be used in the initial classification of adults.[1,32] If total cholesterol is less than 200 mg/dL, then the patient has a *desirable blood cholesterol level* (Table 28–6). Cholesterol levels between 200 and 239 mg/dL are classified as *borderline-high blood cholesterol levels,* and assessment of risk factors (Table 28–7) is needed to more clearly define disease risk. Blood cholesterol levels of 240 mg/dL and above are classified as *high blood cholesterol levels.* If the total cholesterol is below 200 mg/dL and the HDL is above 40 mg/dL, no further follow-up is recommended for patients without known CHD and who have fewer than two risk factors. In patients with evidence of CHD or other clinical atherosclerotic disease, the LDL goal is less than 100 mg/dL and most patients will require diet and/or drug intervention. For patients with very high risk (known CHD and multiple risk factors) the LDL goal may be set <70 mg/dL, based on evidence from newer studies.[32] Decisions regarding classification and management are based on the LDL-C levels as outlined in Table 28–8. An increasing number of persons have the metabolic syndrome that is characterized by abdominal obesity, atherogenic dyslipidemia (elevated triglycerides, small LDL particles, low HDL-C), raised blood pressure, insulin resistance (with

or without glucose intolerance), and prothrombotic and proinflammatory states. ATP III recognizes the metabolic syndrome as a secondary target of risk-reduction therapy after LDL-C has been addressed and if the metabolic syndrome is present, the patient is considered to have a CHD risk equivalent. Other lipid targets include non-HDL goals for patients with triglycerides >200 mg/dL. Non-HDL is calculated by subtracting HDL from total cholesterol, and the targets are 30 mg/dL greater than LDL for each risk stratum. Non-HDL takes into consideration atherogenic particles such as remnant lipoproteins and intermediate-density lipoproteins that are not measured in routine clinical laboratory testing.[33] HDL-raising has potential benefit, but no specific goals are set in the current guidelines and the evidence is modest to support aggressively increasing HDL levels.[34]

The Expert Panel on Children and Adolescents of the NCEP recommends screening in higher-risk children (positive family history or parental high blood cholesterol, ≥240 mg/dL).[35] The American Academy of Pediatrics categorizes total and LDL cholesterol into Acceptable (<75th percentile; total cholesterol <170 mg/dL), Borderline (75th–95th percentile; total cholesterol 170–199 mg/dL, LDL cholesterol 11–129 mg/dL) and Elevated (>95th percentile; total cholesterol >200 mg/dL, LDL cholesterol >130 mg/dl).[35] The rationale, in part, for this approach is based on the recognition that atherosclerosis begins in the childhood and adolescent years as documented in the pathobiologic determinants of atherosclerosis in youth (PDAY) and the Bogalusa studies.[36] Similarly, if children with high blood lipids or lipoprotein levels are identified, and the levels in the parents are unknown, the parents should be screened as well, as they are likely to be at high risk. Racial and gender differences do exist in the determination of lipoprotein fractions, and these factors should be considered in screening. Use of the serum cholesterol level alone may be of insufficient specificity or sensitivity, depending on the cut points used in screening, and other discretionary factors, such as hypertension, smoking, obesity, high-fat diet, and use of cholesterol-raising medication, may be needed to correctly identify children at risk. Presently, children over the age of 10 years are candidates for drug therapy if a trial of diet (6 months to 1 year) proves to be inadequate and LDL-C remains above 190 mg/dL, or above 160 mg/dL, if two or more risk factors or CHD are present in the child or adolescent, or if there is a history of premature CHD. In children with diabetes mellitus, pharmacologic treatment should be considered when LDL cholesterol is ≥130 mg/dL.[35] The Dietary Intervention Study in Children (DISC) in pubertal children found that a fat-restricted diet modestly lowered LDL-C and maintained psychologic well-being, and dietary changes are acceptable to children.[37,38] Although bile acid sequestrants have been the recommended drugs for this population, clinical trials demonstrate that statin therapy is effective and well tolerated in pediatric populations.[3940] The long-term consequences of drug therapy in this population are unknown. In special instances, familial hypercholesterolemia (particularly the homozygous form), or the existence of CHD or two or more risk factors in the child, would prompt the earlier institution of drug therapy after a trial of dietary intervention.

TREATMENT

DESIRED OUTCOMES

The goals of therapy expressed as LDL-C levels and the level of initiation of therapeutic lifestyle change (TLC) and drug therapy are provided in Table 28–8 for adults and children, respectively. While these goals are surrogate endpoints, the primary reason to institute TLC and drug therapy is to reduce the risk first or recurrent events such as MI, angina, heart failure, or ischemic stroke or other forms of peripheral arterial disease such as carotid stenosis or abdominal aortic aneurysm.

GENERAL APPROACH[1]

Establishing targeted changes and outcomes with consistent reinforcement of goals and measures at follow-up visits to attain goals are important to reduce barriers for optimizing TLC and pharmacologic therapy. 3 TLC should be implemented in all patients prior to considering drug therapy. The components of TLC include reduced intakes of saturated fats and cholesterol, dietary options to reduce LDL such as plant stanols and sterols and increased soluble fiber intake, weight reduction, and increased physical activity. In general, physical activity of moderate intensity 30 minutes per day for most days of the week should be encouraged.[41,42] Patients with known CAD or at high risk should be evaluated before undertaking vigorous exercise. Weight and body mass index (BMI) should be determined at each visit and lifestyle patterns to induce a weight loss of 10% should be discussed in persons who are overweight. All patients should also be counseled to stop smoking and to meet the Joint National Committee VII guidelines for control of hypertension.

NONPHARMACOLOGIC THERAPY

Individualized diet counseling that provides acceptable substitutions for unhealthy foods and ongoing reinforcement by a registered dietitian are necessary for maximal effect. The objectives of dietary therapy are to progressively decrease the intake of total fat, saturated fatty acids (i.e., saturated fat), and cholesterol, and to achieve a desirable body weight. Typical American diets now include 13% to 20% of total calories from saturated fat and a cholesterol intake of 350–450 mg/d, both in excess of a "heart healthy" diet for normal Americans, let alone patients with a lipid disorder. Excessive dietary intake of cholesterol and saturated fatty acids leads to decreased hepatic clearance of LDL and deposition of LDL and oxidized LDL in peripheral tissues. The targeted saturated fatty acids have carbon chain lengths of 12 (lauric acid), 14 (myristic acid), and 16 (palmitic acid). The rationale for using a nutritionally balanced low-fat, low-cholesterol diet for the treatment of hypercholesterolemia is based on these principles: (a) it represents a reasonable extension of the diet recommended for the general public; (b) it progressively decreases the major cholesterol-raising constituent of the diet; (c) it precludes large intakes of polyunsaturated fats; and (d) it facilitates weight reduction by removing foods of high caloric density.[43–46]

Dietary expertise in providing a wide range of options and suggestions in preparation of food can make the difference between a good and an inadequate response to diet. Information concerning eating out in a healthy fashion and advice for shopping are also important factors for success in diet therapy. An example is being aware of products with misleading labels such as coffee creamers that state they contain "no cholesterol," when they may contain hydrogenated (saturated) fats or oils (e.g., palmitic acid, palm kernel oil, or coconut oil), which makes them undesirable because of their saturated fat content. Variations in polyunsaturated and saturated fat and cholesterol intake influence the LDL concentration, but the amount of cholesterol has been found to have a greater effect than the proportion of polyunsaturated or saturated fat. There were also racial differences in elevation of LDL with high saturated fat diets being greater in whites than in other racial groups. The isomeric form of fatty acids is also important.[43] Fatty acids with the *cis* configuration are the preferred substrate for the ACAT reaction and significantly increase hepatic LDL receptor clearance while

TABLE 28-9 Macronutrient Recommendations for the TLC Diet

Component[a]	Recommended Intake
Total fat	25–35% of total calories
Saturated fat	Less than 7% of total calories
Polyunsaturated fat	Up to 10% of total calories
Monounsaturated fat	Up to 20% of total calories
Carbohydrates[b]	50–60% of total calories
Cholesterol	<200 mg per day
Dietary Fiber	20–30 grams per day
Plant sterols	2 grams per day
Protein	Approximately 15% of total calories
Total calories	To achieve and maintain desirable body weight

[a]Calories from alcohol not included.
[b]Carbohydrates should derive from foods rich in complex carbohydrates such as whole grains, fruits, and vegetables.

reducing LDL cholesterol production rate. The *trans* isomeric form cannot be used by ACAT and is biologically inactive with no effect on LDL concentration.

Ideally, therapeutic TLC including reduced intake of saturated fats and cholesterol, increased stanol/sterol and fiber intake, weight reduction, and increased physical activity should be used to attain lower LDL-C and to achieve reductions in CHD risk (Table 28–9). TLC may obviate the need for drug therapy, augment LDL-lowering drug therapy, and allow for lower doses. Weight control plus increased physical activity reduces risk beyond LDL-cholesterol lowering, is the primary management approach for the metabolic syndrome, raises HDL, and reduces non-HDL cholesterol.[47,48] Many persons should be given a three-month trial (two visits spaced 6 weeks apart) of dietary therapy and TLC before advancing to drug therapy unless patients are at very high risk (severe hypercholesterolemia, known CHD, CHD risk equivalents, multiple risk factors, strong family history). Although changes in blood lipid levels may change before three months, adoption of a different eating pattern may require a longer period of time. It is important to involve all family members, especially if the patient is not the primary person preparing food. The NCEP and AHA both have excellent Internet-based resources to aid patients in altering their diet in a culturally sensitive manner (*http://www.americanheart.org/presenter.jhtml?identifier=1200009; http://www.nhlbi.nih.gov/health/index.htm*). If all of the recommended dietary changes from NCEP are made, the estimated reduction, on average, in LDL would range from 20–30%.[1] Adherence to diet and inter-individual variability in macronutrient intake would obviously influence the eventual LDL level achieved. Based on the NHANES data, less than one-half of the patients who should be instructed on a heart healthy diet receive any dietary instructions.

Other dietary interventions or diet supplements may be useful in certain patients with lipid disorders. Increased intake of soluble fiber in the form of oat bran, pectins, certain gums, and psyllium products can result in useful adjunctive reductions in total and LDL cholesterol, but these dietary alterations or supplements should not be substituted for more active forms of treatment. Total daily fiber intake should be about 20–30 g/d, with about 25% or 6 g/d, being soluble fiber.[1] Studies with psyllium seed in doses of 10–15 g/d show reductions in total and LDL cholesterol ranging from about 5% to 20%.[49,50] They have little or no effect on HDL-C or triglyceride concentrations. These products may also be useful in managing constipation associated with the bile acid sequestrants. Psyllium binds cholesterol in the gut but also reduces hepatic production and clearance. Fish oil supplementation provides an increased amount of the omega-3 polyunsaturated fatty acids such as eicosapentaenoic acid and docosahexaenoic acid. In epidemiologic studies, ingestion of large amounts of cold water, oily fish is associated with a reduction in CHD risk, but it is unclear whether the same advantage is conferred with commercially prepared fish oil products. Each 20 gm per day ingestion of fish lowers CHD risk by 7% and eating fish once weekly or more should reduce CHD mortality.[51] Fish oil supplementation has a fairly large effect in reducing triglycerides and VLDL-C, but it either has no effect on total and LDL cholesterol or may cause elevations in these fractions. Other actions of fish oil may account for their protective effects. These effects include quantitative and qualitative alterations in the synthesis of prostanoid substances, changes in immune function and cellular proliferation, and potential antioxidative actions.[52] Responses noted with fish oil are further discussed under drug therapy.[53]

Fat substitutes such as Olestra (Olean, sucrose polyester, Procter and Gamble), a mixture of hexa-, hepta-, and octa-esters formed from the reaction of sucrose with long-chain fatty acids, are approved by the FDA as a nondigestible, nonabsorbable, noncaloric fat substitute for snack foods. Olestra is heat stable, an advantage over several other fat substitutes, enabling it to be used in the preparation of fried and baked foods. It is similar in composition to triglycerides, but Olestra is not hydrolyzed in the gastrointestinal tract by pancreatic lipase, and, consequently, is not taken up by the intestinal mucosa. The principal adverse effects associated with Olestra use are bloating, flatulence, diarrhea, and "anal leakage." Because of the ability of Olestra to solubilize lipophilic substances, there has been concern over potential drug interactions in which lipophilic drugs (e.g., cyclosporin or colchicine) or vitamins (vitamins A, D, E, and K) are solubilized in Olestra and excreted in the feces.

Recent studies have demonstrated the LDL-lowering effect of plant sterols, which are isolated from soybean and tall pine tree oils. Ingestion of 2–3 grams per day will reduce LDL by 6–15%.[1] Plant sterols can be esterified to unsaturated fatty acids (creating sterol esters) to increase lipid solubility. Hydrogenating sterols produces plant stanols and, with esterification, stanol esters. The efficacy of plant sterols and plant stanols is considered to be comparable. Because lipids are needed to solubilize stanol/sterol esters, they are usually available in commercial margarines. The presence of plant stanols/sterols is listed on the food label. When margarine products are used, persons must be advised to adjust caloric intake to account for the calories contained in the products. Benecol® (McNeil), as an example, is a butter-like spread that contains a plant stanol ester, an ingredient that can lower cholesterol and which is derived from plant stanols found naturally in small amounts in foods like wheat, rye, and corn.[54] In August 2007, the Food and Drug Administration issued a warning about the consumption of red yeast rice and red yeast rice/policosonal containing products. These products contained lovastatin that could interact with other drugs and would have the same toxicity of statins but would not be recognized by the consumer and the reduction in LDL is minimal.[55]

Drug therapy is indicated following an adequate trial of TLC changes as outlined in Table 28–8.

PHARMACOLOGIC THERAPY

There are now numerous randomized, double-blinded clinical trials demonstrating that reduction of LDL reduces CHD event rates in primary prevention, secondary intervention, and in angiographic trials.[56] Generally speaking, for every 1% reduction in LDL, there is a 1% reduction in CHD event rates.[1] However, if treatment extends beyond the typical duration of a clinical trial (2–5 years), the accumulated benefit could be greater. Elevations of HDL of 1% result in approximately a 2% reduction in CHD events.[14,57] Of interest, angiographic trials, which typically cause small changes in luminal diameter (e.g., about a 0.04-mm difference in change between

TABLE 28-10 Effects of Drug Therapy on Lipids and Lipoproteins

Drug	Mechanism of Action	Effects on Lipids	Effects on Lipoproteins	Comment
Cholestyramine, colestipol, and colesevelam	↑ LDL catabolism ↓ Cholesterol absorption	↓ Cholesterol	↓ LDL ↑ VLDL	Problem with compliance; binds many co-administered acidic drugs
Niacin	↓ LDL and VLDL synthesis	↓ Triglyceride and ↓ Cholesterol	↓ VLDL, ↓ LDL, ↑ HDL	Problems with patient acceptance; good in combination with bile acid resins; extended release niacin causes less flushing and is less hepatotoxic than sustained release
Gemfibrozil, fenofibrate, clofibrate	↑ VLDL clearance ↓ VLDL synthesis	↓ Triglycercide and ↓ cholesterol	↓ VLDL, ↓ LDL, ↑ HDL	Clofibrate causes cholesterol gall stones; modest LDL lowering; raises HDL; gemfibrozil inhibits glucuronidation of simvastatin, lovastatin, and atorvastatin
Lovastatin, pravastatin, simvastatin, fluvastatin, atorvastatin, rosuvastatin	↑ LDL catabolism; inhibit LDL synthesis	↓ Cholesterol	↓ LDL	Highly effective in heterozygous familial hypercholesterolemia and in combination with other agents
Ezetimibe	Blocks cholesterol absorption across the intestinal border	↓ Cholesterol	↓ LDL	Few adverse effects; effects additive to other drugs

placebo and active treatment), result in fewer clinical events such as MI or the need for revascularization. This unexpected finding suggests that plaque size and luminal encroachment by plaque may be less important than the effects that cholesterol lowering may have on the activity in the plaque and endothelial dysfunction. These studies provide a strong rationale for attempting to lower plasma cholesterol and LDL in patients with hypercholesterolemia.

4 Although many efficacious lipid-lowering drugs exist, none is effective in all lipoprotein disorders, and all such agents are associated with some adverse effects.[58] Lipid-lowering drugs can be broadly divided into agents that decrease the synthesis of VLDL and LDL, agents that enhance VLDL clearance, agents that enhance LDL catabolism, agents that decrease cholesterol absorption, agents that elevate HDL, or some combination of these characteristics (Table 28–10). Table 28–11 lists recommended drugs of choice for each lipoprotein phenotype and alternate agents. Table 28–12 lists available products and their doses.

Treatment of type I hyperlipoproteinemia is directed toward reduction of chylomicrons derived from dietary fat with the subsequent reduction in plasma triglycerides. Total daily fat intake should be no more than 10–25 g/d, or approximately 15% of total calories. Secondary causes of hypertriglyceridemia (see Table 28–5) should be excluded or, if present, the underlying disorder should be treated appropriately. Type V hyperlipoproteinemia also requires a stringent restriction of the fat component of dietary intake. In addition, drug therapy is indicated, as outlined in Table 28–11, if the response to diet alone is inadequate. Medium-chain triglycerides, which are absorbed without chylomicron formation, may be used as a dietary supplement for caloric intake if needed for types I and V. Hepatic fibrosis has been reported with medium-chain triglycerides. Omega-3 fatty acids may be useful in lipoprotein lipase deficiency in some patients. In patients with apolipoprotein C-II deficiency, infusion of plasma may normalize plasma triglyceride levels.

	Niacin	Fish oils

BAR, bile acid resins; fibrates include gemfibrozil or fenofibrate
[a]BAR are not used as first-line therapy if triglycerides are elevated at baseline, since hypertriglyceridemia may worsen with BAR alone.

Primary hypercholesterolemia (familial hypercholesterolemia, familial combined hyperlipidemia, type IIa hyperlipoproteinemia) is treated with the bile acid resins or sequestrants (BAR, colestipol, cholestyramine, and colesevelam), HMG Co-A reductase inhibitors (statins), niacin, or eztimibe. 5 Of these choices, statins are first choice because they are the most potent LDL lowering agents. Statins interrupt the conversion of HMG-CoA to mevalonate, the rate-limiting step in de novo cholesterol biosynthesis, by inhibiting HMG-CoA reductase (see Fig. 28–3). Currently available products include lovastatin, pravastatin, simvastatin, fluvastatin, atorvastatin, and pitvastatin.[59] Rosuvastatin is currently the most potent statin on the market. Table 28–13 lists the pharmacokinetic properties of the statins.[60] The plasma half-lives for all the statins are reported to be short except for atorvastatin and rosuvastatin, and this may account for their potency. In CURVES, the largest head-to-head comparison of statins, atorvastatin was found to be the most potent drug for lowering total cholesterol and LDL-C, with reductions in LDL-C of 38%, 46%, 51%, and 54% for the 10-, 20-, 40-, and 80-mg doses, respectively.[61] Metabolic studies with statins in normal volunteers and patients with hypercholesterolemia suggest reduced synthesis of LDL-C, as well as enhanced catabolism of LDL mediated through LDL receptors, as the principal mechanisms for lipid-lowering effects. Total and LDL cholesterol are reduced in a dose-related fashion by 30% or more on average when added to dietary therapy, with the effects being more pronounced in non-familial than in familial hypercholesterolemia. 6 Combination therapy with bile acid sequestrants and lovastatin is rational as LDL receptor numbers are increased, leading to greater degradation of LDL-C; intracellular synthesis of cholesterol is inhibited, and

TABLE 28-12 Comparison of Drugs Used in the Treatment of Hyperlipidemia

Drug	Manufacturer	Dosage Forms	Usual Daily Dose	Maximum Daily Dose
Cholestyramine(Questran)	BMS	Bulk powder/4-g packets	8 g tid	32 g
Cholestyramine(Questran Light)	BMS	Bulk powder/4-g packets		
Cholestyramine Cholybar)	Parke-Davis	4-g resin per bar		
Colestipol hydrochloride (Colestid)	Upjohn	Bulk powder/5-g packets	10 g bid	30 g
Colesevelam (Welchol)	Sankyo	625 mg tablets	1,875 mg bid	4,375 mg
Niacin	Various	50-, 100-, 250-, and 500-mg tablets; 125-, 250-, and 500-mg capsules	0.5–1 g tid	6 g/day
Extended release niacin (Niaspan)	Kos	500, 750, and 1000 mg tablets	1–2 g/day	2,000 mg
Extended release niacin + lovastatin (Advicor)[a]	Kos	Niacin/lovastatin 500 mg/20 mg tablets Niacin/lovastatin 750 mg/20 mg tablets Niacin/lovastatin 1000 mg/20 mg tablets	Niacin/lovastatin 500 mg/ 20 mg	Niacin/lovastatin 1000 mg/ 20 mg
Fenofibrate (Tricor and others)	Abbott, various	67, 134, and 200 mg capsules (micronized); 54 and160 mg tablets; 40, 120 mg tablets; 50, 160 mg tablets	54 mg or 67 mg	201 mg
Gemfibrozil (Lopid)	Parke-Davis	300-mg capsules	600 mg bid	1.5 g
Lovastatin (Mevacor)	MSD	20- and 40-mg tablets	20–40 mg	80 mg
Pravastatin (Pravachol)	Bristol-Myers Squibb	10- and 20-mg tablets	10–20 mg	40 mg
Simvastatin (Zocor)	MSD	5, 10, 20, 40 and 80-mg tablets	10–20 mg	80 mg
Atorvastatin (Lipitor)	Pfizer	10 mg tablets	10 mg	80 mg
Rosuvastatin (Crestor)	Astra-Zeneca	5- and 10-mg tablets	5 mg	40 mg
Pitavastatin (Livalo)	Kowa	1, 2, and 4 mg tablets	2 mg	4 mg
Ezetimibe (Zetia)	MSD	10 mg tablet	10 mg	10 mg
Atorvastatin/amlodipine (Caduet)	Pfizer	Atorvastatin/amlodipine 10 mg/5 mg Atorvastatin/amlodipine 20 mg/5 mg Atorvastatin/amlodipine 40 mg/5 mg Atorvastatin/amlodipine 80 mg/5 mg Atorvastatin/amlodipine 10 mg/10 mg Atorvastatin/amlodipine 20 mg/10 mg Atorvastatin/amlodipine 40 mg/10 mg Atorvastatin/amlodipine 80 mg/10 mg	Atovastatin/amlodipine 10 mg/5 mg	Atovastatin/amlodipine 80 mg/10 mg
Pravastatin/aspirin (Pravigard PAC)	BMS	Pravastatin/aspirin 20 mg/81 mg Pravastatin/aspirin 20 mg/325 mg Pravastatin/aspirin 40 mg/81 mg Pravastatin/aspirin 40 mg/325 mg Pravastatin/aspirin 80 mg/81 mg Pravastatin/aspirin 80 mg/325 mg		
Simvastatin/ezetimibe (Vytorin)	Merck/Schering-Plough	Simvastatin/ezetimibe 10 mg/ 10 mg Simvastatin/ezetimibe 20 mg/ 10 mg Simvastatin/ezetimibe 40 mg/ 10 mg	Simvastatin/ezetimibe 20 mg/10 mg	Simvastatin/ezetimibe 40 mg/10 mg
Omega-3 acid ethyl esters (Lovaza)	Reliant	Eicosapentaenoic acid (EPA) 465 mg, docosahexaenoic acid (DHA) 375 mg	4 1 gram capsules QD or 2 1 gram capsules BID	4 1 gram capsules QD or 2 1 gram capsules BID

Legend: bid indicates twice daily; probucol is no longer on the market in the U.S.; gemfibrozil, fenofibrate, and lovastatin are available as generic products. BMS, Bristol-Myers Squibb; MSD, Merck Sharp & Dohme.

[a]The manufacturer does not recommend use of the fixed combination as initial therapy of primary hypercholesterolemia or mixed dyslipidemia. It is specifically indicated in patients receiving lovastatin alone plus diet who require an additional reduction in triglyceride levels or increase in HDL-cholesterol levels; it is also indicated in those treated with niacin alone who require additional decreases in LDL cholesterol.

enterohepatic recycling of bile acids is interrupted. Combination therapy with a statin plus eztimibe is also rational, since eztimibe inhibits cholesterol absorption across the gut border and adds 12–20% further reduction when combined to a statin or other drugs.[62] However, the combination of a statin and eztimibe has not been shown to affect surrogate endpoints such as carotid intimal medial thickness (CIMT), even with further reduction in LDL cholesterol.[63] Elevation of serum transaminase levels (primarily alanine aminotransferase) to greater than three times the upper limit of normal occurs in approximately 1.3% of patients on moderate to high doses of statins, and serious muscle toxicity occurs in <0.6% of patients.[64] Meta-analysis of placebo-controlled studies with statins demonstrate a low risk of abnormal ALT or CK and a low risk of myopathy without or with rhadomyolysis.[65] Lens opacities have been

Isoenzyme refers to the specific isoenzyme in the cytochrom P450 system which is responsible for the metabolism of each drug. Pharmacokinetic parameters in this table are based on studies and reviews presented in the literature.

reported with lovastatin. However, in the age groups studied, these abnormalities are common and tend to wax and wane with time irrespective of drug therapy, and no statistical association is known to exist. As a category of monotherapy, the HMG-CoA reductase inhibitors are the most potent total and LDL cholesterol-lowering agents and among the best tolerated.[64,65] In an analysis of more than 75,000 patients allocated to statins in clinical trials, Alsheikh-Ali et al. found that risk of statin-associated elevated liver enzymes or rhabdomyolysis is not related to the magnitude of LDL-C lowering. A highly significant inverse relationship between achieved LDL-C levels and rates of newly diagnosed cancer was observed (R^2 = 0.43, p = 0.009).[66] The WHO Foundation Collaborating Centre for International Drug Monitoring has issued a report suggesting that a rare relationship may exist between statin use and the onset of upper motor neuron diseases such as amyotrophic lateral sclerosis but this association remains uncertain.[67] Statin use is associated with a small risk of diabetes (9%).[68] There are numerous pharmacokinetic and pharmacodynamic differences among statins and patients that give rise to variable response to therapy.[69]

The primary action of BAR is to bind bile acids in the intestinal lumen, with a concurrent interruption of enterohepatic circulation of bile acids and a markedly increased excretion of acidic steroids in the feces. This decreases the bile acid pool size and stimulates hepatic synthesis of bile acids from cholesterol. Depletion of the hepatic pool of cholesterol results in an increase in cholesterol biosynthesis and an increase in the number of LDL receptors on the hepatocyte membrane. The increased number of receptors stimulates an enhanced rate of catabolism from plasma and lowers LDL levels. CETP, which is correlated with total and LDL cholesterol concentrations, is also reduced by BAR, perhaps by interfering with hepatic microsomal cholesterol content, but this effect is not as great as with statins.[70] Patients with homozygous familial hypercholesterolemia genetically lack the ability to increase synthesis of LDL receptors and bile acid resins are generally ineffective. The increase in hepatic cholesterol biosynthesis may be paralleled by increased hepatic VLDL production and consequently, bile acid resins may aggravate hypertriglyceridemia in patients with combined hyperlipidemia. Gastrointestinal complaints of constipation, bloating, epigastric fullness, nausea, and flatulence are most commonly reported.[1] With intensive education, patients can learn to tolerate resins on a long-term basis as evidenced by adherence in clinical trials to active drug regimens. However, in routine clinical practice 40% or more of patients will discontinue therapy within one year but with pharmacists' interventions, adherence rates can be improved.[71,72] These adverse effects can be managed by increasing the fluid intake, modifying the diet to increase bulk, and using stool softeners. The other major limiting complaint is the gritty texture and bulk; these problems may be minimized by mixing the powder with orange drink or juice. Tablet forms of bile acid sequestrants should help in improving compliance with this form of therapy, whereas resin does not improve compliance.[73] Other potential adverse effects include impaired absorption of fat-soluble vitamins A, D, E, and K; hypernatremia and hyperchloremia; gastrointestinal obstruction; and reduced bioavailability of acidic drugs such as coumarin anticoagulants, nicotinic acid, thyroxine, acetaminophen, hydrocortisone, hydrochlorothiazide, loperamide, and possibly iron. Hyperchloremic metabolic acidosis, hypernatremia, and gastrointestinal obstruction have been reported almost exclusively in children, and malabsorption of fat-soluble vitamins is probably most common with high doses (e.g., 30 g/d of cholestyramine) of the bile acid resins. Drug interactions may be avoided by alternating administration times with an interval of six hours or greater between the bile acid resin and other drugs. Colestipol and cholestyramine have comparable side effects; however, colestipol may have better palatability because it is odorless and tasteless. Colesevelam is the newest BAR and total and LDL-C reduction is dose related. The adverse effects are qualitatively similar to the older BAR but may occur less often. Because of adverse effects occurring commonly with BAR at higher doses, BARs are increasingly used in combination with other drugs, as low doses are tolerated well and they work in a complementary fashion with other agents.

Niacin (nicotinic acid) may also be used in primary hypercholesterolemia in combination with bile acid sequestrants or as monotherapy for this disorder and others (Table 28–11). Niacin reduces the hepatic synthesis of VLDL, which in turn leads to a reduction in the synthesis of LDL. Factors responsible for decreased production of VLDL include inhibition of lipolysis with a decrease in free fatty acids in plasma, decreased hepatic esterification of triglycerides, and a possible direct effect on the hepatic production of apolipoprotein B.[74] The complementary action of niacin and bile acid sequestrants to increase catabolism and decrease synthesis of LDL may account for the additive effects of this combination in hyperlipidemia. Niacin also increases HDL by reducing its catabolism. Niacin selectively decreases hepatic removal of HDL apoA-I but not removal of cholesterol esters, thereby increasing the capacity of retained apoA-I to augment reverse cholesterol transport in isolated hepatic cells. The principal use of niacin is for mixed hyperlipemia or as a second-line agent in combination therapy for hypercholesterolemia. It is also considered to be the first-line agent or an alternative for the treatment of hypertriglyceridemia and diabetic dyslipidemia.[75,76] There are numerous smaller trials suggesting that lower doses of niacin may be combined with statins or gemfibrozil to minimize adverse effects and maximize response. One meta-analysis showed that combination therapy was no more effective than high dose statin therapy.[77] These combinations require careful monitoring because interactions do occur.

Niacin has many adverse drug reactions that occur commonly; fortunately, most of the symptoms and biochemical abnormalities seen do not require discontinuation of therapy. Cutaneous flushing and itching appear to be prostaglandin-mediated and can be reduced by aspirin 325 mg given shortly before niacin ingestion.[1,78] Flushing seems to be related to rising plasma concentrations of niacin; taking the dose with meals and slowly titrating the dose upward may minimize these effects. Laropiprant is a selective antagonist of the prostaglandin D(2) receptor subtype 1 (DP1), which may mediate niacin-induced vasodilation. Coadministration of laropiprant 30, 100, and 300 mg with extended-release (ER) niacin significantly lowered flushing symptom scores (by approximately 50% or more) and also significantly reduced malar skin blood flow measured by laser Doppler perfusion imaging.[79,80] Gastrointestinal intolerance and flushing are common problems. Acanthosis nigricans, a darkening of the skin in skinfold areas and an external marker of insulin resistance, may be seen with high doses of niacin. Sustained-release products may minimize these complaints in some patients, but controlled trials with regular-release products do not demonstrate much of a difference between sustained- and regular-release products. The only legend form of niacin, Niaspan® (Abbott), is an extended release form of niacin with pharmacokinetics intermediate between instant and sustained-release products which are sold as food supplements rather than legend products. In controlled trials, Niaspan® is reported to have fewer dermatologic reactions and has a low risk for hepatoxicity. When combined with statins, this combination produces large reductions in LDL and increases in HDL.[81] Potentially important laboratory abnormalities occurring with niacin therapy include elevated liver function tests, hyperuricemia, and hyperglycemia. Recent experience with niacin in diabetes suggests that some diabetic patients do not have worsened glycemic control with dose-titration and sustained-release products.[82] Body mass index and fasting plasma glucose predict loss of blood glucose control.[83] With less than 3 grams per day, the degree of liver function

test elevation is generally not marked and often transient, and a temporary reduction in dosage frequently corrects the problem. Niacin-associated hepatitis is more common with sustained-release preparations, and their use should be restricted to patients intolerant of regular-release products.[82,84] Sustained-release products are often more expensive and given the lack of data for reduced adverse effects and increased incidence of hepatitis, regular-release products should always be used first. Preexisting gout and diabetes may be exacerbated by niacin; these patients should be monitored more closely and their medication titrated appropriately. Patients with well-controlled Type 2 diabetes mellitus do not have significant changes in glycemic control with niacin at doses of 2 grams per day or less.[84] Niacin is contraindicated in patients with active liver disease. Dry eyes and other ophthalmologic complaints are also occasionally noted. Concomitant alcohol and hot drinks may magnify flushing and pruritus with niacin and they should be avoided at the time of ingestion. Nicotinamide should not be used in the treatment of hyperlipidemia, as it does not effectively lower cholesterol or triglyceride levels.

Combined hyperlipoproteinemia (type IIb) may be treated with statins, niacin, or gemfibrozil combinations to lower LDL cholesterol without elevating VLDL and triglycerides. Niacin is the most effective agent and may be combined with a bile acid sequestrant. Bile acid resins alone in this disorder may elevate VLDL and triglycerides, and their use as single agents for treating combined hyperlipoproteinemia should be avoided. Fibric acid (gemfibrozil, fenofibrate) monotherapy is effective in reducing VLDL, but a reciprocal rise in LDL may occur, and total cholesterol values may remain relatively unchanged. Gemfibrozil reduces the synthesis of VLDL and to a lesser extent, apolipoprotein B, with a concurrent increase in the rate of removal of triglyceride-rich lipoproteins from plasma. Plasma HDL concentrations may rise 10% to 15% or more with fibrates. Fenofibrate may have fewer drug interactions than gemfibrozil but fenofibrate has been reported to worsen renal function.[85] Ezetimibe could also be used in combination therapy in Type IIb. Gastrointestinal complaints with fibric acid derivatives occur in 3% to 5% of patients; rash in 2% of patients; dizziness in 2.4% of patients; and transient elevations in transaminase levels and alkaline phosphatase in 4.5% and 1.3% of patients, respectively.[86] Gemfibrozil and probably fenofibrate may enhance the formation of gallstones associated with an increase in the lithogenic index; however, the rate is low (0.5–7%) and similar to that seen with placebo in the Helsinki heart study.[86] Fibric acid derivatives may potentiate the effects of oral anticoagulants and international normalized ratio (INR) should be monitored very closely with this combination.

Type III hyperlipoproteinemia may be treated with fibric acid derivatives or niacin. Although fibric acid derivatives have been suggested as the drugs of choice for this disorder, given the lack of data supporting its efficacy in altering cardiovascular mortality in the major studies on hypercholesterolemia, and numerous, well-documented, and serious adverse effects, it is reasonable to consider niacin. Gemfibrozil increases the activity of lipoprotein lipase and reduces to a lesser extent the synthesis or secretion of VLDL from the liver into the plasma. A myositis syndrome of myalgia, weakness, stiffness, malaise, and elevations in creatinine phosphokinase and aspartate aminotransaminase is seen with the fibric acid derivatives, and it seems to be more common in patients with renal insufficiency.[86] Enhanced hypoglycemic effects are reported to occur when fibric acid derivatives are given to patients on sulfonylurea compounds, but the mechanisms for these interactions are not well understood.

Two fibric acid derivatives (gemfibrozil and fenofibrate) are approved in the United States. Both reduce LDL-C by 20% to 25% in heterozygous familial hypercholesterolemia. The response of LDL-C, HDL-C, and triglycerides to this category of drug is very dependent on the specific lipoprotein type (e.g., type IIa versus IIb) and the baseline triglyceride concentration.[87]

As a potential alternative therapy, for this phenotype, numerous epidemiologic and normal volunteer studies have found that diets high in omega-3 polyunsaturated fatty acids (from fish oil), mostly commonly eicosapentaenoic acid, reduce cholesterol, triglycerides, LDL-C, and VLDL-C, and may elevate HDL-C.[53] The effects of fish oil on lipoprotein metabolism are mediated through a reduction in VLDL production and suppression of VLDL apolipoprotein B. In patients with hypertriglyceridemia, either phenotypes type IIb or type V, a diet high in omega-3 fatty acids given for 4 weeks reduced cholesterol 27% and 45%, and triglyceride 64% and 79%, in the type IIb and type V patients, respectively.[51] A diet high in eicosapentaenoic acid given to hyperlipidemic hemodialysis patients resulted in significant decreases in cholesterol and triglycerides for as long as 13 weeks. Fish oil supplementation may be most useful in patients with hypertriglyceridemia; however, its role in treatment is not well defined. Potential complications of fish oil supplementation, such as thrombocytopenia and bleeding disorders, have been noted, especially with high doses (eicosapentaenoic acid 15–30 g/d); and well-controlled trials are needed to determine if fish oils are safe and effective before their use may be broadly recommended. Based on a recent meta-analysis, fish consumption lowers the risk of CHD but nutricueticals have not been adequately tested.[51] Recently, a prescription form of concentrated fish oil, Lovaza®, has become available.[53] This product lowers triglycerides by 14% to 30% and raises HDL by about 10%, depending on baseline values.

Combination drug therapy may be considered after adequate trials of monotherapy and for patients documented compliant to the prescribed regimen. Two or three lipoprotein profiles at 6-week intervals should confirm lack of response prior to initiation of combination therapy. Cholestyramine may be added in patients with fasting hypertriglyceridemia, but it should not be used as the initial drug, because triglycerides are likely to increase. Contraindications to and drug interactions with combined therapy should be carefully screened, as well as consideration of the extra cost of drug product and monitoring that may be required. In general, a statin and a BAR or niacin with a BAR provide the greatest reduction in total and LDL cholesterol. Regimens intended to increase HDL levels should include either gemfibrozil or niacin, and it should be remembered that statins combined with either of these drugs may result in a greater incidence of hepatotoxicity or myositis. This is particularly important for statins that are eliminated via cytochrome 3A4 or through glucuronidation.[60] Familial combined hyperlipidemia may respond better to a fibric acid and a statin than to a fibric acid and a BAR.[88]

Severe forms of hypercholesterolemia, such as familial hypercholesterolemia, familial defective apolipoprotein B-100, severe polygenic hypercholesterolemia, familial combined hyperlipidemia, and familial dysbetalipoproteinemia (type III)—may require more intensive therapy. In particular, familial hypercholesterolemia patients often require combination therapy (two or three drugs) and are managed with surgical therapy (partial ileal bypass), plasmapheresis (LDL-apheresis), and liver transplantation (to replace LDL receptors).

HYPERTRIGLYCERIDEMIA

It is important to remember that lipoprotein pattern types I, III, IV, and V are associated with hypertriglyceridemia, and that these primary lipoprotein disorders and underlying diseases should be excluded prior to implementing therapy (see Table 28–5). In a national survey, approximately one third of participants tested had

a triglyceride concentration exceeding 150 mg/dL.[89] A positive family history of CHD is important in identifying patients at risk for premature atherosclerosis.[17,90] If a patient with CHD has elevated triglycerides, the associated abnormality is probably a contributing factor to CHD and should be treated.[32]

High serum triglycerides (see Tables 28–6 and 28–11) should be treated by achieving desirable body weight, consumption of a low saturated fat and cholesterol diet, regular exercise, smoking cessation, and restriction of alcohol (in selected patients). ATP III identifies the sum of LDL + VLDL (termed *non-HDL* [total cholesterol - HDL]) as a secondary target of therapy in persons with high triglycerides (≥200 mg/dL).[1,32] This approach is used when triglycerides exceed 200 mg/dL and accounts for atherogenic particles carried in VLDL and remnant particles. The goal for non-HDL in persons with high serum triglycerides can be set at 30 mg/dL higher than that for LDL on the premise that a VLDL level ≤30 mg/dL is normal. 7 In patients with borderline-high triglycerides but with accompanying risk factors of established CHD disease, family history of premature CHD, concomitant LDL elevation or low HDL, and genetic forms of hypertriglyceridemia associated with CHD (familial dysbetalipoproteinemia, familial combined hyperlipidemia), drug therapy with niacin should be considered. Niacin may be used cautiously in diabetics based on the results of the ADMIT trial, which found that triglycerides were reduced by 23%, HDL-C increased by 29%, there was only a slight increase in glucose (mean 8.7 mg/dL), and no change in hemoglobin A_{1c}.[91] Elevated body mass index and plasma glucose predict loss of glycemic control.[83] Alternative therapies include gemfibrozil or fenofibrate, statins, and fish oil.[17,92,93] Fibrates may increase LDL, and their use in borderline-high triglyceridemia requires careful monitoring to detect this deleterious change in lipid profile. Statins may also be used, because they provide modest reductions in triglycerides and modest elevations in HDL. Higher doses of statins may reduce HDL as well as LDL and triglycerides with the amount of reduction related to the baseline concentration and dose.[17,93] The goal of therapy in this situation is to lower triglycerides and VLDL particles that may be atherogenic, increase HDL, and reduce LDL.

Very high triglycerides are associated with pancreatitis and other consequences of the chylomicron syndrome. At this level of elevation of triglycerides, a genetic form of hypertriglyceridemia often coexists with other causes of elevated triglycerides such as diabetes. Dietary fat restriction (10% to 20% of calories as fat), weight loss, alcohol restriction, and treatment of the coexisting disorder are the basic elements of management. Drugs useful in hypertriglyceridemia include gemfibrozil or fenofibrate, niacin, and higher potency statins (atorvastatin, rosuvastatin, pitvastatin, and simvastatin). Gemfibrozil or fenofibrate are the preferred drugs in diabetics because of the effect of niacin on glycemic control unless the newer extended-release forms are used. Fenofibrate may be preferred in combination with statin therapy since it does not impair glucuronidation and minimizes potential drug interactions. Success in treatment is defined as a reduction in triglycerides below 500 mg/dL.[1]

LOW HDL CHOLESTEROL

Low HDL is a strong independent risk predictor of CHD. ATP III redefined low HDL-C as <40 mg/dL, but specified no goal for HDL-C raising.[1] Low HDL may be a consequence of insulin resistance, physical inactivity, Type 2 diabetes, cigarette smoking, very high carbohydrate intake, and certain drugs (see Table 28–5). 8 In low HDL, the primary target remains LDL according to ATP III, but emphasis shifts to weight reduction, increased physical activity, and smoking cessation, and if drug therapy is required, to fibric acid derivatives and niacin. Niacin has the potential for the greatest increase in HDL and the effect is more pronounced with regular or immediate-release forms than with sustained-release forms.[94]

DIABETIC DYSLIPIDEMIA

Diabetic dyslipidemia is characterized by hypertriglyceridemia, low HDL, and LDL that is minimally elevated. Small, dense LDL (pattern B) in diabetes is more atherogenic than larger, more buoyant forms of LDL (pattern A); routine lipoprotein profiles do not differentiate between pattern A and pattern B.[95–97] Diabetes in ATP III is a CHD risk equivalent and the primary target is LDL with a goal of treatment being to lower LDL-C <100 mg/dL.[1] When LDL is >130 mg/dL, most patients will require simultaneous therapeutic lifestyle changes and drug therapy. When LDL-C is between 100 and 129 mg/dL, intensifying glycemic control, adding drugs for the atherogenic dyslipidemia (fibric acid derivatives, niacin) and intensifying LDL-C-lowering therapy are options. Because the primary target is LDL-C in diabetic dyslipidemia, statins are considered by many to be initial drugs of choice.[1,32] The relative risk reduction for CHD in diabetics versus nondiabetics is greater in the West of Scotland, (37% versus 20%)[98] AFCAPS/TexCAPS (43% versus 36%),[99] CARE (25% versus 23%),[100] and 4S (55% versus 32%) trials.[101] All statins are fairly comparable in triglyceride lowering and because statins differ in potency for LDL reduction, a ratio of LDL reduction to triglyceride reduction can be applied. Statin therapy may protect against the development of diabetes.[29] The most recent trial LDL-lowering in Type 2 diabetes mellitus is the Collaborative Atorvastatin Diabetes Study (CARDS).[102] This was a randomized, double-blind placebo comparison of atorvastatin 10 mg per day versus placebo in 2,838 diabetes patients to reduce first CHD events. Baseline LDL was 118 mg/dL and with atorvastatin LDL fell by 46 mg/dL. The primary end point, a composite of acute CHD death, nonfatal MI, hospitalized unstable angina, resuscitated cardiac arrest, and coronary revascularization or stroke, was reduced by 37%. This study suggests that all diabetics should have a LDL much lower than 100 mg/dL and these results are consistent with the Heart Protection Study analysis of diabetic patients.[103]

Fenofibrate, according to the DIAS trial, reduced the angiographic progression of CAD in type 2 diabetes.[104] Fewer CHD events were seen with fenofibrate compared with placebo but the difference was not significant. Fibric acids principally lower VLDL and triglycerides while increasing HDL with only modest lowering of total and LDL cholesterol. On occasion, fibric acid derivatives may increase LDL levels. Fibric acid derivatives tend to improve glucose tolerance, in contrast to niacin; the greatest effect has been seen with bezafibrate. The Helsinki Heart Study found gemfibrozil to be most effective in diabetic dyslipidemia.[105] Although the effect of statins on triglycerides and HDL abnormalities commonly seen in diabetes is less than with fibric acids, the subgroup analyses cited earlier suggest that they reduce CHD risk significantly. In the Action to Control Cardiovascular Risk in Diabetes (ACCORD) the combination of a statin and fenofibrate in patients with type 2 diabetes did not reduce the rate of fatal cardiovascular events, nonfatal myocardial infarction, or nonfatal stroke compared to simvastatin alone.[106] Cholestyramine in diabetic patients may result in lower LDL levels, but VLDL and triglyceride levels, which are commonly elevated in diabetes, may be further increased in this population. Resins may aggravate constipation, which is common in diabetics. As demonstrated in the ADMIT and ADVENT trials, immediate-release and extended-release niacin are very effective in raising HDL and lowering triglycerides and LDL.[91,107]

SPECIAL CONSIDERATIONS

Elderly

Hypercholesterolemia is an independent risk factor for CHD in the elderly (>65 years old), as it is in the younger patient. The attributable risk, which is the difference in absolute rates of CHD between segments of the population with higher or lower serum cholesterol levels, increases with age. Older patients potentially benefit to a greater extent from cholesterol lowering than younger populations. Data from studies of elderly men in a variety of settings are consistent with a relative risk of at least 1.5 in the highest quartile compared to the lowest quartile of cholesterol levels and a relative risk reduction of 22% for heart-related mortality.[108,109,110] Treatment of hypercholesterolemia in the elderly may bring about a comparable reduction in absolute risk to that obtained in younger persons.[1] Subgroup analyses of the West of Scotland (primary) and 4S (secondary) intervention studies show that elderly patients have lower CHD risk reduction (relative risk reduction of 27% and 29%, respectively) as compared to younger patients (relative risk reduction of 40% and 39%, respectively).[98,111] The Framingham study suggests that elderly women are at higher risk because of high blood cholesterol levels, but no other large studies included women; and their risks or benefits from cholesterol reduction are not well defined. Primary prevention in younger patients requires about two years before reduction in CHD risk is apparent, and this lag time should be taken into consideration in patient selection for therapy. Non-lipid CHD risk factors do not decline in relative risk with aging, and aggressive management of the modifiable non-lipid risk factors is important in the older patient. High-risk elderly patients are less likely to be prescribed statins and their potent benefits are not realized.[112] Because most women with CHD are elderly and also at risk for osteoporosis, they are logical candidates for diet therapy with consideration of calcium intake consistent with osteoporosis prevention, exercise, and perhaps estrogen replacement therapy. Recent evidence suggests that statins may reduce the risk of osteoporosis; however, there are conflicting data from various studies.[113]

Drug therapy in principle differs little from younger patients, and older patients respond to lipid-lowering drugs as well as younger patients.[114,115] Based on the Heart Protection Study with more elderly patients than any other trial, simvastatin 40 mg per day produced the same CHD event rate reduction in patients over 70 years of age as in younger patients.[116] The gain in life expectancy may be small depending on the age at the start of treatment and the magnitude of cholesterol reduction. Changes in body composition, renal function, and other physiologic changes of aging may make older patients more susceptible to adverse effects of lipid-lowering drug therapy. In particular, older patients are more likely to have constipation (bile acid resins), skin and eye changes (niacin), gout (niacin), gallstones (fibric acid derivatives), and bone/joint disorders (fibric acid derivatives, statins). Therapy should be started with lower doses and titrated up slowly to minimize adverse effects.

Women

Cholesterol is an important determinant of CHD in women, but the relationship is not as strong as that seen in men. HDL may be a more important predictor of disease in women.[4] LDL and HDL genetic regulation in women and men does not appear to be different. Based on the Nurses' Health Study, obesity is an important determinant of CHD in women, with the relative risk being 3.3 in the highest Quetelet index (weight in kilograms divided by the square of the height in meters) as compared to the lowest category (i.e., <21 vs ≥29); low HDL levels usually accompany obesity.[117] No major differences exist in the influence of exercise, alcohol ingestion, and smoking on lipid levels between men and women. Women in the highest tertile of cholesterol appear to be more responsive to dietary therapy than those in the lower tertiles, and more responsive than formulas based on men predict.

Based on the HERS[118] and WHI trials[119–121], recently published national guidelines recommended similar types of lifestyle and risk factor goals and interventions as recommended by NCEP for the entire population.[4] Hormone therapy may continue to have a role for postmenopausal symptoms, however, a notable exception is hormone replacement therapy and heart protection. Combined estrogen plus progestin hormone therapy should not be initiated to prevent CVD in postmenopausal women. Combined estrogen plus progestin hormone therapy should not be continued to prevent CVD in postmenopausal women. Other forms of menopausal hormone therapy (e.g., unopposed estrogen) should not be initiated or continued to prevent CVD in postmenopausal women pending the results of ongoing trials. Results of the WISDOM trial confirm a lack of benefit as seen in HERS and WHI.[122] In a recent, post-hoc analysis of the WHI, women who initiated hormone therapy closer to menopause tended to have reduced CHD risk compared with the increase in CHD risk among women more distant from menopause, but this trend did not meet statistical signifance.[119] Based on the Justification for the Use of Statins in Prevention: An Intervention Trial Evaluating Rosuvastatin (JUPITER) trial, women experience the same benefit of LDL cholesterol lowering as men with rosuvastatin.[123]

Cholesterol and triglyceride levels rise progressively throughout pregnancy, with an average increment in cholesterol of 30–40 mg/dL occurring around the 36th to 39th weeks. Triglyceride levels may go up by as much as 150 mg/dL. Drug therapy is not instituted nor is it usually continued during pregnancy. If the patient is very high risk, a bar acid resin may considered since there is no systemic drug exposure.[1] Statins are category X and are contraindicated. Ezetimibe might be an alternative, since it is a Category C drug (animal studies have shown that the drug exerts teratogenic or embryocidal effects, and there are no adequate, well-controlled studies in pregnant women, or no studies are available in either animals or pregnant women) but no data are available in humans. Dietary therapy is the mainstay of treatment, with emphasis on maintaining a nutritionally balanced diet as per the needs of pregnancy.

Children

Drug therapy in children is not recommended until the age of 8 years or older, and the guidelines for institution of therapy and the goals of therapy are different from those in adults.[124] Younger children are generally managed with therapeutic lifestyle changes until after the age of 2 years.[1,46] Although bile acid sequestrants have been recommended in the past as first line therapy, there is now evidence that statins are safe and effective in children and provide greater lipid lowering than BAR.[125–127,128] Severe forms of hypercholesterolemia (e.g., familial hypercholesterolemia) may require more aggressive treatment.

CONCURRENT DISEASE STATES

Nephrotic syndrome, end-stage renal disease and nephrotic syndrome, and hypertension compound the risk of dyslipidemia and may present difficult-to-treat lipid abnormalities. Abnormalities of lipoprotein metabolism in the nephrotic syndrome include elevated total and LDL cholesterol, Lp(a), VLDL, and triglycerides. The apolipoprotein C-III to C-II ratio is elevated, consistent with greater lipoprotein lipase inhibitor activity, and the extent of hypoalbuminemia is correlated with dyslipidemia. The basic abnormality appears to be one of overproduction of LDL-apoB from VLDL, rather than reduced clearance of LDL-C and related proteins. Protein restriction and a "vegan" diet corrects lipid abnormalities to some extent. Statins have been shown to be

effective in reducing elevated total and LDL cholesterol in the nephrotic syndrome, although the levels do not usually return to normal.[129] Fibric acid derivatives and statins reduce small, dense LDL-C by different mechanisms, suggesting a potential role for combination therapy to optimize lowering of small, dense LDL-C and remnant lipoproteins. Statins appear to safe and effective for lowering LDL cholesterol in renal insufficiency but they may not affect CHD endpoints.[130,131]

Renal insufficiency without proteinuria leads to hypertriglyceridemia, slightly elevated total and LDL cholesterol (particularly with chronic ambulatory peritoneal dialysis), and low HDL levels (especially during hemodialysis). These abnormalities are thought to be caused by a deficiency in apolipoprotein C-II, perhaps as a result of sustained use of heparin during hemodialysis and depletion of lipoprotein lipase, carbohydrate-induced obesity and hypertriglyceridemia, loss of carnitine during hemodialysis, use of acetate buffer (acetate is a precursor to fatty acid synthesis) during hemodialysis, and decreased LCAT activity during hemodialysis. Dialysis does not correct the lipid abnormalities. Renal transplantation may correct lipid abnormalities in some patients. However, in others, the use of transplantation-related medications such as corticosteroids, cyclosporine, and certain antihypertensive agents (see Chapters 19 and 98) may aggravate the lipid abnormalities. Cyclosporine interferes with the metabolism of statins metabolized by cytochrome P450 3A4 (Table 28–13), and patients need to be observed closely for myositis and worsening renal function. Of interest, correction of lipid abnormalities may improve renal hemodynamics. Pravastatin and fluvastatin may be safer than other statins, but this needs to be validated in larger, long-term trials. Diet will modify lipoprotein levels and polyunsaturated fatty acids may have a role in impeding the progression of renal disease as well as the cardiovascular complications. Bile acid sequestrants do not correct the lipid abnormalities seen in renal insufficiency. Lovastatin or its active metabolite may accumulate in renal insufficiency, and lower doses of reductase inhibitors should be used to avoid adverse effects. Gemfibrozil may be used with caution as its pharmacokinetics are unchanged and it lowers triglycerides and increases HDL.[132] Statins (simvastatin, lovastatin, and atorvastatin) and fibric acid derivatives may increase the risk of severe myopathy, and attention to symptoms of myositis is needed. Niacin may also be useful in nondiabetic patients with renal insufficiency.

Hypertensive patients have a greater-than-expected prevalence of high blood-cholesterol levels and, conversely, patients with hypercholesterolemia have a higher than expected prevalence of hypertension caused by the metabolic syndrome. Recommendations for the management of hypertension in patients with hypercholesterolemia include avoiding the use of drugs that elevate cholesterol such as diuretics and β-blockers and using agents that are either lipid-neutral or that may reduce cholesterol slightly (see Chapter 19).[1] Bile acid sequestrants may bind to thiazide diuretics and some β-blockers, and may interfere with their absorption; reaction may be avoided by giving the antihypertensive 1 hour before or 4 hours after the resin. Niacin may magnify the hypotensive effects of vasodilators.

PHARMACOECONOMIC CONSIDERATIONS

⑩ The clinical benefits of lipid-lowering therapy for primary and secondary intervention are now well established, based on the results of studies showing a reduction in CHD morbidity and mortality.[133,134,135] The balance of benefits and costs has been examined in a few studies. The cost per year of life saved has been estimated to range from less than $10,000 to over $1 million dollars, depending on the presence or absence of CHD, age of the patient, baseline total or LDL-C level and reduction in cholesterol, and number of risk factors present. In general, intervention in patients with known CHD, those who have CHD risk equivalents, or those with a 10-year risk of 10% to 20%, are cost-effective with statin therapy, while other types of therapy may be cost-effective if certain assumptions concerning compliance, efficacy, and so forth, are met. The range for secondary intervention based on the 4S study is $3,800 for a 70-year-old man with a high cholesterol level to $27,400 per year of life gained for a middle-aged woman with an average cholesterol level.[136] In contrast, primary prevention in men based on the West of Scotland trial averages about $35,000 per year of life gained.[137] These studies demonstrate that primary and secondary interventions are well within the accepted boundary of less than $50,000 for a medical intervention to be considered cost-effective. Based on the specific lipoprotein phenotype, fibric acid derivatives, niacin, or combination therapy of statins plus BAR may be cost-effective. Cost-effectiveness is maximized by treating high-risk patients and those with established CHD.

Specialty lipid clinics have become increasingly popular and many use pharmacists to provide direct patient care in this setting. An interesting recent analysis shows that a specialty clinic may be more expensive ($659 ± $43 versus $477 ± $42 per patient, $P < .001$) than usual care. However, the overall cost-effectiveness is improved when expressed as program costs per unit (mmol/L) reduction in the LDL-C, a measure of cost-effectiveness that was significantly lower for specialized care ($758 ± $58 versus $1,058 ± $70, $P = .002$)because more patients achieve their targeted goal.[138] Project ImPACT demonstrated that pharmacists, working collaboratively with patients and physicians can improve persistence and compliance and that nearly two-thirds of patients achieved their NCEP lipid goal.[139] Other programs show similar trends.[72,140,141]

OTHER THERAPIES

Partial ileal bypass has been used in severe heterozygous and homozygous familial hypercholesterolemia; however, it is ineffective in the latter case. Ileal bypass removes the site of bile acid reabsorption, depleting the bile acid pool and increasing the catabolism of cholesterol. A randomized trial of diet versus surgery program on the surgical control of the hyperlipidemias (POSCH), reported that total and LDL cholesterol were decreased (23.3% and 37.7%, respectively) and HDL increased (4.3%) in patients who had undergone ileal bypass for hypercholesterolemia.[142] Overall death was delayed by nearly 3 years ($P = .032$) and CHD mortality was delayed by nearly 4 years ($P = .046$) by surgery, as compared to the control group. Revascularization procedures were delayed by an average of 7 years ($P < .001$). Post-surgery diarrhea was more common in the surgical group, as was the rate of kidney stones (4% versus 0.4%), gallstones (10% versus 2%), and bowel obstruction (13.5% versus 3.6%).

Portacaval shunts have been used to decrease the formation of LDL-C and reductions of 10% to 20% have been reported. Plasma exchange combined with niacin was found to reduce plasma cholesterol levels by about 50% in homozygous familial hypercholesterolemia over 5 years, and coronary atherosclerosis did not progress as documented by angiography. LDL-apheresis, selective removal of LDL-C via a filtering system, plus statin therapy is effective in LDL-C and appears to affect the progression of vascular disease. LDL-apheresis may be combined with statin therapy for greater effect. Combined liver and heart transplantation in homozygous familial hypercholesterolemia reduces total and LDL cholesterol concentrations from about 1100 and 900 mg/dL to about 300 and 185 mg/dL, prior to and after surgery, respectively. Liver transplantation replaced the missing LDL receptors, enhanced catabolism, and reduced lipoprotein synthesis in this patient.

TABLE 28-14 Primary Prevention Trials with Lipid-Lowering Drugs

Trial	F/U (yr)	N	Treatment	Control Events	Treatment Events	*P* Value	RRR	ARR	NNT
AFCAPS/TexCAPS	5	6,605	Lovastatin 20–40 mg	5.5%	3.5%	<0.001	36.4%	2.0%	50
Helsinki	5	4,081	Gemfibrozil 1200 mg	4.1%	2.7%	<0.02	34.0%	1.4%	71
LRC-CPPT	7.4	3,806	Cholestyramine 24 g	9.8%	8.1%	<0.05	17.3%	1.7%	59
Oslo	5	1,232	Diet + smoking cessation	4.2%	2.5%	0.03	40.5%	1.7%	59
WOSCOPS	4.9	6,595	Pravastatin 40 mg	7.8%	5.5%	<0.001	29.5%	2.3%	43
ALLHAT	4.8	10,355	Usual care Pravastatin 40 mg	10.4%	9.3%	0.16	9%	1.1%	91
WHI	5.2	16,608	Usual care Diet, CEE 0.625 mg + MPA 2.5 mg	1.5%	1.9%	0.05	1.29[a]	0.4%	200[b]
WHI	5.2	16,608	Usual care Diet, CEE 0.625 mg	3.7%	3.3%	NS	9%	0.4%	250
CARDS	4	2,838	Atorvastatin 10 mg	9.0%	5.8%	0.001	37%	3.2%	32

[a]HR, hazard ratio. The risk of CHD was increased by 29%.

[b]Number needed to harm since CEE + MPA was worse than placebo.

SUMMARY OF MAJOR STUDIES

9 Primary and secondary prevention diet and drug trials have been performed to determine whether lowering of cholesterol will prevent CHD. Table 28–14 and Table 28–15 summarize these trials. A number of earlier angiographic studies demonstrated that cholesterol reduction leads to regression of atherosclerosis and plaque stabilization. Most of the primary and secondary studies were double blinded, randomized, and placebo controlled, lasting for 5 years or longer, and most had sufficient patient numbers to be meaningful. Exceptions to these qualifications were seen in the early studies such as the Newcastle and Edinburgh trials, which were small and generally did not show much benefit; and the Coronary Drug Project (CDP) using dextrothyroxine, which was terminated early due to adverse effects on CHD mortality. The Helsinki heart study, using gemfibrozil, resulted in a reduction in nonfatal MI, which was the primary contributor to reduced CHD incidence (Table 28–14).[16]

Total and LDL cholesterol were reduced an average of 13.4% and 20.3%, respectively, by cholestyramine in the LRC-CPPT, and the reduction of lipid levels was related to the amount of drug ingested (e.g., 1 to 2 packets, 5.4% reduction in total cholesterol, versus 5 or more packets, 19.0% reduction).[143] The prescribed dose of cholestyramine was 24 g, or 6 packets, per day. The cholestyramine group experienced a 19% reduction in risk ($P < .05$) of the primary end point: Definite CHD death and/or definite nonfatal MI, reflecting a 24% reduction in definite CHD death and a 19% reduction in nonfatal MI. Other end points were reduced by 25%, 20%, and 21% for new positive exercise tests, angina, and coronary bypass

TABLE 28-15 Secondary Prevention Trials with Lipid-Lowering Drugs

Trial	F/U (yr)	N	Treatment	Control Events	Treatment Events	*P* Value	RRR	ARR	NNT
VA-HIT	5.1	2,531	Gemfibrozil 1200 mg	23.7%	17.3%	0.006	22%	4.4%	23

surgery, respectively. Death from all causes was not significantly reduced by cholestyramine secondary to more accidents and violence in this group. The mean falls in total and LDL cholesterol in the cholestyramine group were 8% and 12% relative to levels in placebo-treated men, providing evidence that for every 1% reduction in cholesterol, a 2% decline in CHD mortality can be realized.

AFCAPS/TexCAPS, a primary prevention trial conducted in 6,605 men and women aged 57 to 63 years with average total cholesterol and LDL (<221 mg/dL and <150 mg/dL, respectively) who were treated with lovastatin 20–40 mg/d for 5.2 years, a 37% reduction ($P < .001$) was shown in the risk for first acute major coronary event (fatal or nonfatal MI, unstable angina, or sudden cardiac death).[99] The need for revascularization procedures was also reduced by 33% ($P < .001$). The implications of this trial are enormous. Potentially millions of "normal" people could benefit from lipid-lowering with statins based on these results. The number of patients that need to be treated (NNT, **Table 28–14**) for primary prevention ranges from 43 in the West of Scotland trial to 71 in the Helsinki Heart Study. This range is within the typical boundary used for treatment decisions and described previously; cost-effectiveness is achieved routinely in patients with moderate to high risk. The Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT-LLT) tested pravastatin 40 mg per day versus placebo in hypertensive patients with at least one CHD risk factor. Pravastatin did not reduce either all-cause mortality or CHD significantly when compared with usual care in older participants with well-controlled hypertension and moderately elevated LDL-C. The results may be due to the modest differential in total cholesterol (9.6%) and LDL-C (16.7%) between pravastatin and usual care compared with prior statin trials supporting cardiovascular disease prevention.[144] The Women's Health Initiative trial proved to be disappointing, with no beneficial effects on CHD event reduction in the hormone replacement arm (conjugated equine estrogens (CEE) + medroxyprogesterone) or the CEE alone arm compared to placebo.[118,120] Women did experience greater risk for thromboembolism and a slight increase in breast cancer and a reduced risk of hip fracture. Consequently, hormone replacement therapy can no longer be recommended for cardiovascular protection.[4] Publication of the recent WISDOM trial found that when combined hormone therapy (n = 2196) was compared with placebo (n = 2189), there was a significant increase in the number of major cardiovascular events (7 vs 0, $P = 0.016$) and venous thromboembolism (22 vs 3, hazard ratio 7.36 [95% CI 2.20 to 24.60]) confirming the findings of HERS and WHI. There were no statistically significant differences in numbers of breast or other cancers, cerebrovascular events, fractures, and overall death.[122]

Niacin in the CDP significantly reduced definite, nonfatal MI as compared to placebo (10.1% versus 13.9%), whereas clofibrate did not reduce death from any cause or nonfatal or fatal MI at the 5-year follow-up period.[145]

One of the most important studies published in the last few years is the 4S trial, a secondary intervention trial in a large number of patients.[146] Simvastatin, 20–40 mg/d, reduced LDL cholesterol by 35% and reduced the risk of death from any cause by 30%. Coronary deaths were also reduced with simvastatin (relative risk, 0.58; confidence interval, 0.46–0.73). Therapy was also shown to be effective in women (18% to 19% of patients enrolled) and in the elderly (≥60 years). Indeed, the relative risk of death or major coronary event was reduced to a greater extent in the elderly than in younger patients. Death from noncardiovascular causes was similar for simvastatin and placebo (2.1% and 2.2%, respectively). The survival curves for simvastatin and placebo began to separate at 1 year and became more divergent with additional follow-up. The 4S study clearly demonstrates the benefit in cholesterol lowering and placates long-held fears of death from non-CHD causes. The long-term intervention with pravastatin in ischemic disease (LIPID) study ($N = 7498$ men and 1516 women) has investigated the effect of pravastatin on CHD mortality in patients with prior MI or unstable angina and mean cholesterol level of 219 mg/dL over 6 years.[147] Pravastatin reduced the risk of CHD mortality by 24% (8.3% versus 6.4%, $P = .0004$) and total mortality by 23% (14.1% versus 11.0%, $P = .00002$); stroke was also reduced by 20% (4.3% versus 3.5%, $P = .22$) as well as a reduction in the need for coronary artery bypass graft (11.3% versus 8.9%, $P = .0001$) or percutaneous transluminal coronary angioplasty (5.3% versus 4.4%, $P = .04$).

The Veterans Administration High-Density Lipoprotein intervention trial (VA-HIT) was a double-blind trial that compared gemfibrozil (1200 mg/d) with placebo in 2,531 men with CHD, an HDL cholesterol level of ≤40 mg/dL, and an LDL cholesterol level of ≤140 mg/dL.[148] The primary study outcome was nonfatal MI or death from coronary causes. The median follow-up was 5.1 years. At 1 year, the mean HDL cholesterol level was 6% higher, the mean triglyceride level was 31% lower, and the mean total cholesterol level was 4% lower in the gemfibrozil group than in the placebo group. LDL cholesterol levels did not differ significantly between the groups. A primary event occurred in 21.7% of the patients assigned to placebo and in 17.3% of the patients assigned to gemfibrozil. The overall reduction in the risk of an event was 4.4 percentage points, and the reduction in relative risk was 22% ($P = 0.006$). This trial presents the strongest evidence to date that raising HDL-C and lowering triglycerides reduces risk for CHD.

The Atorvastatin Versus Revascularization Treatments (AVERT) study compared atorvastatin 80 mg/d with percutaneous transluminal coronary angioplasty.[149] The follow-up period was 18 months. Of the patients who received aggressive lipid-lowering treatment with atorvastatin, 13% had ischemic events, as compared to 21% of the patients who underwent angioplasty. The incidence of ischemic events was thus 36% lower in the atorvastatin group over an 18-month period ($P = 0.048$, which was not statistically significant after adjustment for interim analyses). This reduction in events was because of a smaller number of angioplasty procedures, coronary-artery bypass operations, and hospitalizations for worsening angina (the most common end point). As compared to the patients who were treated with angioplasty and usual care, the patients who received atorvastatin had a significantly longer time to the first ischemic event ($P = 0.03$). In low-risk patients with stable CAD, aggressive lipid-lowering therapy is at least as effective as angioplasty and usual care in reducing the incidence of ischemic events.

Pravastatin in the elderly individuals at risk for vascular disease (PROSPER) studied men and women in the age range of 70–82 years and found that pravastatin 40 mg per day reduced CHD events by 24% with no affect on cognitive function.[150] A more recent trial, TIMI-22 (also known as PROVE-IT, Pravastatin or Atorvastatin Evaluation and Infection Therapy) enrolled 4,162 patients who had been hospitalized for an acute coronary syndrome within the preceding 10 days and compared 40 mg of pravastatin daily (standard therapy) with 80 mg of atorvastatin daily (intensive therapy).[151] An intensive lipid lowering statin regimen with atorvastatin 80 mg per day provided greater protection against death or major cardiovascular events than did a standard regimen. This study clearly points to "lower is better" for LDL concentration and will likely lead to revision in guideline goals to lower LDL levels. The Treatment to New Targets (TNT) assessed the efficacy and safety of lowering LDL cholesterol levels below 100 mg per deciliter (2.6 mmol per liter) in patients with stable coronary heart disease (CHD).[152,153] Intensive lipid-lowering therapy with 80 mg of atorvastatin per day in patients with stable CHD provides significant clinical benefit beyond that afforded by treatment with 10 mg of atorvastatin per day, providing further evidence that intensive lipid lowering brings greater benefits.

Statins reduce the incidence of strokes among patients at increased risk for cardiovascular disease. Whether they reduce the risk of stroke after a recent stroke or transient ischemic attack (TIA) was addressed by Stroke Prevention by Aggressive Reduction in Cholesterol Levels (SPARCL). During a median follow-up of 4.9 years, 265 patients (11.2 percent) receiving atorvastatin 80 mg/day and 311 patients (13.1 percent) receiving placebo had a fatal or non-fatal stroke (5-year absolute reduction in risk, 2.2 percent; adjusted hazard ratio, 0.84; 95 percent confidence interval, 0.71 to 0.99; P = 0.03; unadjusted P = 0.05).[154] JUPITER randomized healthy patients to rosuvastatin on placebo on the basis of elevated CRP and found a 55% reduction in vascular events (event rate 1.11 vs. 0.51 per 100 person-years; hazard ratio 0.45, p <0.0001).[23]

CLINICAL CONTROVERSIES

The CETP inhibitor torcetrapib was associated with a substantial increase in HDL cholesterol and decrease in LDL cholesterol. It was also associated with an increase in blood pressure, and there was no significant decrease in the progression of coronary atherosclerosis. The lack of efficacy may be related to the mechanism of action of this drug class or to molecule-specific adverse effects. Other means of raising HDL cholesterol (HDL mimetics, which include ApoA1 mutants and peptide mimetics of ApoA1 and HDL Milano A, a synthetic form of HDL) still hold hope of HDL modification leading a reduction in clinical events.

The enzyme acyl-coenzyme A:cholesterol acyltransferase (ACAT) esterifies cholesterol in a variety of tissues. In some animal models, ACAT inhibitors have antiatherosclerotic effects. Unfortunately, when tested in clinical trials, ACAT inhibition is not an effective strategy for limiting atherosclerosis and may promote atherogenesis.[155]

Statins differ in their pharmacokinetic properties and in pleotropic effects (i.e., non-lipid lowering). The contribution of lipid lowering alone (a class effect) versus other effects (anti-inflammatory, antithombotic, etc.) continues to create controversy.

Proteinuria has been associated with high dose rosuvastatin therapy (40 mg/day), but a review of a clinical trial database revealed an increase in eGFR for rosuvastatin-treated patients was consistent across all major demographic and clinical subgroups of interest, including patients with baseline proteinuria, baseline eGFR <60 ml/min/1.73 m2, and in patients with hypertension and/or diabetes.[156]

Mipomersen, an investigational apoliprotein B synthesis inhibitor, reduced LDL cholesterol in patients with homozygous hypercholesterolemia by nearly 25% with the most common adverse events being injection site pain.[157]

The role of non-traditional risk factors (hsCRP, homocysteine, etc.) continues to be clarified and may lead to recommendations for the use of these tests in patient evaluation.

EVALUATION OF THERAPEUTIC OUTCOMES

Short-term evaluation of therapy for hyperlipidemia is based on response to diet and drug treatment as measured in the clinical laboratory by total cholesterol, LDL cholesterol, HDL cholesterol, and triglycerides for patients being treated for primary intervention, as well as on response to secondary intervention. The interval for follow-up is dependent on the severity of illness, and patients with known CAD or multiple risk factors should be monitored more closely. Less commonly used laboratory measurements include C-reactive protein, homocysteine, apolipoprotein B, and Lp(a) levels. Because many patients being treated for primary hyperlipidemia have no symptoms and may not have any clinical manifestations of a genetic lipid disorder such as xanthomas or eruptions, monitoring and outcome are solely laboratory based. In patients treated for secondary intervention, symptoms of atherosclerotic cardiovascular disease, such as angina or intermittent claudication, may improve over months to years. If patients have xanthomas or other external manifestations of hyperlipidemia, these lesions should regress with therapy. Lipid measurements should be obtained in the fasted state to minimize interference from chylomicrons, and once the patient is stable, monitoring is needed at intervals of 6 months to 1 year. The goals for LDL and HDL cholesterol are provided in Table 28–8.

Patients with multiple risk factors and established CHD should also be monitored and evaluated for progress in managing their other risk factors such as hypertension, smoking cessation, exercise and weight control, and glycemic control if diabetic. The goals are to maintain a blood pressure of below 130/80 mm Hg or less (presence of diabetes or renal insufficiency), stop smoking, maintain an ideal body weight, exercise for at least 20 minutes three or more times per week, and keep plasma glucose below 100 mg/dL (threshold for glucose intolerance). Invasive evaluation, such as cardiac catheterization, is useful in patients with established CHD and is typically used for planning revascularization rather than monitoring of lipid-lowering therapy.

Evaluation of dietary therapy is part of the outcome evaluation for treating hyperlipidemia and the assistance of a dietitian is recommended. Use of diet diaries and recall survey instruments enable information about diet to be collected in a systematic fashion and may improve patient adherence to dietary recommendations. Patients on resin therapy should have a FLP panel checked every 4–8 weeks until a stable dose is reached; triglycerides should be checked at the stable dose to ensure they have not increased. Niacin requires baseline liver function tests, uric acid and glucose; repeat tests are appropriate at doses of 1,000–1,500 mg per day. Symptoms of myopathy or diabetes-like symptoms should be investigated and may require CK or glucose determinations; more frequent monitoring in diabetics may be necessary. A FLP 4–8 weeks after the initial dose or dose changes with statins is appropriate. Liver function tests should be obtained at baseline and periodically thereafter based on package insert information. Recognized experts believe that monitoring for hepatotoxicity and myopathy should be symptom-triggered.[58,65] Ezetimibe requires little specific monitoring. However, with the publication of the SEAS trial, there is concern over the increased risk of cancer.[158] Other studies underway will clarify this issue.

CHAPTER 29

Peripheral Arterial Disease

BARBARA J. HOEBEN AND ROBERT L. TALBERT

KEY CONCEPTS

1. The prevalence of peripheral arterial disease is dependent upon age and the presence of traditional risk factors for cardiovascular disease, and many patients are undiagnosed; undiagnosed patients have substantial risk for coronary and cerebrovascular events.
2. The clinical presentation of peripheral arterial disease is variable and includes a range of symptoms. The two most common characteristics of peripheral arterial disease are intermittent claudication and pain at rest in the lower extremities.
3. The ankle-brachial index (ABI) is a simple, noninvasive, quantitative test that has been proven to be a highly sensitive and specific tool in the diagnosis of peripheral arterial disease.
4. As with any atherosclerotic condition, several risk factors play an important role in the morbidity and mortality of peripheral vascular disease. Many of these risk factors are modifiable with the help of various nonpharmacologic and pharmacologic interventions.
5. Nonpharmacologic interventions such as smoking cessation and walking exercise programs have the ability to positively impact several of the pathophysiologic abnormalities present for patients with peripheral arterial disease.
6. Data proving that antiplatelet therapies can prevent or delay the progression of peripheral arterial disease are currently unavailable. However, aspirin therapy has repeatedly been proven to significantly reduce serious vascular events in these "high-risk" patients and, in the absence of contraindications, is highly recommended.
7. After appropriate exercise therapy and therapeutic lifestyle changes have been implemented, patients who continue to experience severe intermittent claudication may benefit from additional pharmacologic therapy with cilostazol.

Peripheral arterial disease (PAD), the most common form of peripheral vascular disease, is a manifestation of progressive narrowing of arteries due to atherosclerosis.[1] PAD is associated with elevated risk of cardiovascular disease (CVD) morbidity and mortality, even in the absence of prior history of acute myocardial infarction (AMI), stroke, or other manifestations of CVD.[1–3] Patients with PAD have approximately the same relative risk of death from CVD as do patients with a history of coronary or cerebrovascular disease, and PAD should be considered a surrogate marker of subclinical coronary artery disease (CAD) and other vascular territories.[1,4–5] The treatment of PAD focuses on decreasing the functional impairment caused by symptoms of intermittent claudication through nonpharmacologic and pharmacologic therapy and by minimizing the impact of other cardiovascular risk factors.[6]

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

EPIDEMIOLOGY

1 Using the definition of an ankle-brachial index (ABI) of less than 0.9 in either leg, the National Health and Nutrition Examination Survey (NHANES) found a 4.3% prevalence of PAD among adults age 40 years and older in the United States.[2] The prevalence of PAD is highly dependent on age, being infrequent in younger individuals and common in older individuals (Fig. 29–1). In age- and gender-adjusted logistic regression analyses, black race/ethnicity [odds ratio (OR) 2.83] current smoking (OR 4.46), diabetes (OR 2.71), hypertension (OR 1.75), hypercholesterolemia (OR 1.68), and impaired renal function (estimated glomerular filtration rate less than 60 mL/min/1.73 m^2) (OR 2.00) were associated with more prevalent PAD.[2,7] Individuals with PAD are also more likely to have a self-reported history of any CAD or CVD but, interestingly, no association with elevated body mass index. The reported relative risk of death from CVD for patients with PAD is reported to range from 2 to 5.1 for patients with or without CVD and 2.9 to 5.7 for patients with known CVD.[8] CVD accounts for 75% of all deaths in patients with PAD.[9] The risk of death is approximately the same in men and women and is elevated even in asymptomatic patients. Annual mortality is 25% for patients with critical leg ischemia who have the lowest ABI values.[10]

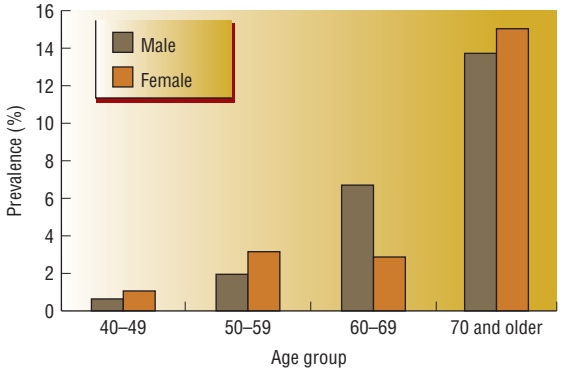

FIGURE 29-1. Prevalence of peripheral arterial disease by age and gender.

More than 5 million (estimated range 4 to 7 million) adults age 40 years or more have PAD. Ninety-five percent of individuals with PAD have at least one cardiovascular risk factor; the majority of patients have multiple risk factors for CVD.[2] Based on the PAD Awareness, Risk, and Treatment: New Resources for Survival (PARTNERS) program, the prevalence of PAD in primary care practices is high, yet physician awareness of the PAD diagnosis is relatively low.[11] In this cross-sectional study, PAD was detected in 29% of 6,979 patients. Eighty-three percent of the patients were aware of their diagnosis but only 49% of their patients' physicians were aware. The reason for this observation is that patient self-report of symptoms and the use of questionnaires to detect PAD are not sufficiently sensitive and specific to reproducibly diagnosis PAD and the cardinal symptom of PAD—intermittent claudication—is present in the minority of patients (1 to 27%).[8,12,13] A simple ABI measurement will identify a large number of patients with previously unrecognized PAD. Atherosclerosis risk factors were very prevalent for PAD patients, but these patients received less intensive treatment for lipid disorders and hypertension and were prescribed antiplatelet therapy less frequently than were patients with CVD. These results demonstrate that underdiagnosed PAD in primary care practice may be a barrier to effective secondary prevention of the high ischemic cardiovascular risk associated with PAD.[11] Because of the systemic nature of atherosclerosis and the high risk of ischemic events, patients with PAD should be considered for secondary prevention strategies including aggressive risk-factor modification and antiplatelet drug therapy.[8,12–16]

ETIOLOGY AND PATHOPHYSIOLOGY

PAD is most commonly a manifestation of systemic atherosclerosis in which the arterial lumen of the lower extremities becomes progressively occluded by atherosclerotic plaque.[9] The major risk factors for the development of atherosclerosis are older age (greater than 40 years), cigarette smoking, diabetes mellitus, hypercholesterolemia, hypertension, and hyperhomocysteinemia.[8,9,12] The arteries most commonly involved, in order of occurrence, are the femoropopliteal-tibial, aortoiliac, carotid and vertebral, splenic and renal, and brachiocephalic.[15] Familial hypercholesterolemia (FH) leading to hypercholesterolemia and elevated low-density lipoprotein (LDL) levels are associated with accelerated development of atherosclerosis earlier and with more severe symptoms (e.g., intermittent claudication) and abnormal blood flow studies compared with controls.[16,17] Intima-media thickness can be used as a surrogate phenotype for cardiovascular risk in FH and carotid and/or femoral artery atherosclerosis results in increased intima-media thickness, and it is correlated to cardiovascular risk in FH patients compared with normolipidemic individuals.

CLINICAL PRESENTATION AND DIAGNOSIS

2 The clinical presentation of PAD is variable, ranging from no symptoms at all (typically early in the disease) to pain and discomfort (Table 29–1). This finding was illustrated in a study by Wang and colleagues,[18] who attempted to aid the diagnosis of PAD by using defined categories of exertional leg pain for patients with and without PAD. They determined that not one of the five categories of leg pain (no pain, pain on exertion and rest, noncalf pain, atypical calf pain, and classic claudication) was sufficiently sensitive or specific to enable a link to a PAD diagnosis. The two most common characteristics of PAD are intermittent claudication (IC) and pain at rest in the lower extremities.[17–19] IC is generally regarded as the primary indicator of PAD. It is described as reproducible fatigue, discomfort, cramping, pain, or numbness in the affected extremities (typically the buttock, thigh or calf) during exercise and is resolved within a few minutes with rest.[17,19–23] Symptoms of IC occur during exercise as the increase in blood flow is limited by occlusive atherosclerotic lesions in the peripheral arteries leading to an inability for oxygen supply to meet the demands of increased metabolic demand by the muscles.[23] Resting pain typically occurs later in the disease when the blood supply is not adequate to perfuse the extremity (critical limb ischemia). This can be felt most often at night in the feet (typically the toes or heel) while the patient is lying in bed.[17–19] Although IC is the primary indicator of PAD, it alone cannot be used to diagnose PAD. As explained by the Inter-Society Consensus for the Management of Peripheral Arterial Disease (TASC II),[23] patients with PAD may not have symptoms of IC because they may have a sedentary lifestyle or some other condition that may be limiting the ability to exercise.

TABLE 29-1 Clinical Presentation of PAD

General
- Patients with peripheral arterial disease (PAD) are likely to be ≥ 40 years of age with hypertension, hypercholesterolemia, diabetes, impaired renal function, a history of coronary artery disease or cardiovascular disease, and/or a history of smoking.

Signs and symptoms
- The clinical presentation of PAD is variable and includes symptoms ranging from no symptoms at all (typically early in the disease) to pain and discomfort.
- The two most common characteristics of PAD are intermittent claudication and pain at rest in the lower extremities.
- Intermittent claudication is generally regarded as the primary indicator in PAD. It has been described as fatigue, discomfort, cramping, pain, or numbness in the affected extremities (typically the buttock, thigh, or calf) during exercise that resolves within a few minutes with rest.
- Physical examination may reveal nonspecific signs of decreased blood flow to the extremities (e.g., cool skin temperature, thickened toenails, lack of hair on the calf, feet, and/or toes).

Laboratory tests
- None specific to PAD.

Other diagnostic tests
- The ankle-brachial index (ABI) is a simple, noninvasive, quantitative test that has been proven to be a highly sensitive and specific (≥90%) tool in the diagnosis of PAD.

Data from references 2, 7, 12, 18, 20–22, 24–27, 29, 31, 85, and 86.

As with any good medical encounter, a detailed patient history of symptoms and atherosclerosis risk factors (e.g., smoking, hypertension, hyperlipidemia, and diabetes) can be helpful in the diagnosis of PAD. Unfortunately, as illustrated by the PARTNERS program, providers who rely on a history alone will miss approximately 85% to 90% of patients with PAD.[24] Therefore, examination of the patient is vital to proper diagnosis. Requesting that the patient remove socks and shoes may reveal nonspecific signs of decreased blood flow to the extremities (e.g., cool skin temperature, shiny skin, thickened toenails, lack of hair on the calf, feet, and/or toes) or, in severe cases, visible sores or ulcers that are slow to heal and may even be black in appearance.[17–19,24–25]

An important criterion for the accurate diagnosis of PAD is the exclusion of other conditions that possess similar signs and symptoms. Differential diagnosis should rule out other neurologic conditions (e.g., peripheral neuropathy), inflammatory conditions (e.g., arthritis), and vascular conditions (e.g., deep venous thrombosis or venous congestion) that may mimic PAD.[17,22,26]

3 The ABI is a simple, noninvasive, quantitative test that has been proven to be a highly sensitive and specific (≥90%) tool in the diagnosis of PAD.[20,27,28] For measurement of the ABI, the patient lies in the supine position as the systolic blood pressure is measured at

the brachial arteries on both arms and the dorsalis pedis and posterior tibial arteries of the legs with a standard sphygmomanometer and a continuous-wave Doppler device. The pressures obtained at the dorsalis pedis and posterior tibial arteries are averaged and divided by the mean measurement taken at the left and right brachial arteries.[8,23,24,29,30] An ABI of 1 is considered normal, while a measurement under 0.9 is consistent with PAD. ABI from 0.7 to 0.9 correlates with mild PAD, 0.4 to 0.7 indicates moderate disease, and under 0.4 denotes severe PAD.[9,21,29] In addition to providing diagnostic information, the ABI measurement has been shown to be a strong predictor of future cardiovascular events associated with PAD.[31,32] The ABI can also be useful after a test of exercise tolerance (e.g., 5 minutes on a treadmill or 30 to 50 repetitions of heel raises). Patients with PAD will demonstrate a significant drop in the ABI after exercise, but their pain will be normal or unchanged. ABI can rule out PAD and suggest alternate diagnoses.[9,21,23,24] ABI can be considered as a useful tool in diagnosing both symptomatic and nonsymptomatic patients at high risk of PAD.[11,33]

Other noninvasive tools are available for the diagnosis of PAD. One study has suggested a calculation that takes into consideration the patient's history of AMI and the number of auscultated and palpated posterior tibial arteries.[34,35] Magnetic resonance angiography (MRA) can be used to examine the presence and location of significant stenosis, or lack thereof, and is a reasonable option for patients who are being considered for surgical revascularization.[36] Similarly, computed tomographic angiography (CTA) can be used to determine the presence of significant stenosis and soft tissue diagnostic information that may be associated with PAD (e.g., aneurysms).[36,37] However, as ABI is a sufficient means of diagnosis, arteriography is not necessary or encouraged.[19,22,28]

TREATMENT

Peripheral Arterial Disease

GOALS OF TREATMENT

PAD is the result of atherosclerotic plaque formation in the arteries that results in decreased blood flow to the legs. Several of the treatment goals for these patients involve the reduction of confounding variables that attribute to the disease process, progress, and eventual outcome. Specific goals should include increasing maximal walking distance, increasing duration of pain-free walking, improving control of comorbid conditions contributing to the morbidity of the condition (e.g., hypertension, hyperlipidemia, and diabetes), improving overall quality of life and reducing cardiovascular complications and death.

GENERAL APPROACH TO TREATMENT

4 As with any atherosclerotic condition, several risk factors play an important role in the morbidity and mortality of PAD. Many of these risk factors are modifiable with the help of various nonpharmacologic and pharmacologic interventions.

NONPHARMACOLOGIC THERAPY

Smoking Cessation

5 Cigarette smoking not only increases the risk of developing PAD and other cardiovascular disorders, but the quantity smoked and the duration can negatively impact disease progression (e.g., increase the risk of amputation) and increase mortality.[8,23,26,31,32,38–41] As a result, providers must advise patients to quit and should offer nonpharmacologic and pharmacologic means to aid the patient in that goal. Individual or group behavior modification therapy with or without the addition of certain antidepressants (e.g., bupropion), varenicline, or nicotine replacement therapies (e.g., gum or patches) has been proven effective in numerous studies. Reassessment of smoking status and progress encouragement at each encounter can help to reemphasize to the patient the vital importance of this lifestyle change.

Exercise

5 Walking exercise programs for patients with PAD have been proven to result in an increase in walking duration and distance, an increase in pain-free walking, and a delayed onset of claudication by 179%.[12,25,26,38,39,42–51] Walking, or any aerobic exercise program conducted under the supervision of a healthcare provider, has the ability to positively impact several of the pathophysiologic abnormalities present in patients with PAD. Benefits of exercise programs include improving diabetes and lipid management, reducing weight, improving blood viscosity and flow, and reducing blood pressure.[6] Walking distance can also be used as a prognostic tool for future outcomes for patients with normal and impaired ABIs. A recent study by de Liefde and colleagues[52] examined patients with normal ABI (≥0.90) and impaired ABI (<0.90) in relation to walking distance. It was demonstrated that walking impairment in conjunction with impaired ABI was associated with higher cardiovascular events, including death. Other studies have likewise observed a link between impaired exercise/walking distance and negative long-term outcomes for patients with PAD.[53,54]

The American College of Cardiology/American Heart Association (ACC/AHA) Guidelines for the Management of PAD recommends supervised exercise training for patients with IC, for a minimum of 30 to 45 minutes, to be performed at least 3 times per week for a minimum of 12 weeks.[36] During exercise sessions, walking should be performed with at a speed and grade of incline to produce the symptoms of IC within 3 to 5 minutes. The patient should stop walking when the symptoms become moderate in intensity, wait for the symptoms to resolve, and then resume walking thus repeating the cycle for the duration of the session.[23] A prospective, observational study performed by Gardner and colleagues concluded that PAD patients with higher physical activity (as measured with a vertical accelerometer) have reduced mortality and cardiovascular events compared with those with low physical activity, regardless of confounders.[48] Exercise treadmill walking testing should be repeated at regular intervals (e.g., quarterly to biannually) to assess improvement or decline in walking duration and distance, as well as the time to pain onset while performing this activity. The type of aerobic activity recommended, as well as the duration and frequency of the activity, should be individually designed on a patient-to-patient basis.

Surgical Interventions

Various surgical procedures are available for patients with severe, debilitating claudication who have attempted, and failed, other means of nonpharmacologic and pharmacologic therapy. The TransAtlantic Inter-Society Consensus (TASC) document on PAD provides clear recommendations for invasive therapy.[28] First, there must be a lack of adequate response to exercise therapy and risk factor modification. Second, the patient must have severe disability from IC resulting in impairment of daily activities. Third, there must be a thorough evaluation of the risks versus benefits of an invasive intervention including probability of success, the anticipated future course of the disease if an intervention is not performed, as well as an evaluation of concomitant disease states.[28] The decision to attempt percutaneous revascularization is often

made with the guidance of diagnostic angiography. Angiography can help to identify the location and size of lesions and provide valuable information as to the likelihood of success with surgical revascularization.[28]

Percutaneous transluminal angioplasty (PTA) is an example of an invasive treatment for PAD. A randomized controlled clinical trial performed by Whyman and colleagues[55] determined that in a 2-year postintervention, PTA outcomes on maximum walking distance and ABI were not significantly different than for patients that had only received daily low-dose ASA ($P>0.05$). Nevertheless, patients who had received PTA had significantly fewer occluded arteries ($P = 0.003$), but the true clinical significance of this finding could not be realized in the time allotted for the study. PTA typically is reserved for patients whose lifestyle and/or job performance are compromised secondary to claudication despite adequate pharmacologic interventions and exercise.[12,40]

Stent placement for PAD patients has also been an area of study and controversy. A metaanalysis examining the use of stent placement versus PTA for the treatment of aortoiliac occlusive disease determined that although stent placement and PTA yielded similar complication and mortality rates, posttreatment ABI was more improved with stents (0.87 with PTA and 0.76 with stents, $P<0.03$), and the risk of long-term failure was 39% less with stent placement.[56] However, other studies have not demonstrated improvement in patency rates in peripheral arteries versus PTA alone.[20] The TASC document provides specific recommendations for PTA, with or without stenting, depending on how diffuse the disease process is, the number and size of the lesions, and the location of the lesions.[28]

For patients with severe IC resulting in critical leg ischemia, physicians may need to discuss alternate surgical interventions including aortofemoral bypass, femoropopliteal bypass, or even amputation.[20,21,42]

PHARMACOLOGIC THERAPY

Hypertension

Hypertension (HTN) is a major risk factor for PAD and can lead to AMI, stroke, heart failure (HF), and death.[14] Current guidelines recommend the treatment goal for blood pressure in patients with PAD to mirror those in patients with documented CVD, 130/85 mm Hg.[14,41] Although the Heart Outcomes Prevention Evaluation study (HOPE trial)[57] demonstrated that angiotensin-converting enzyme (ACE) inhibitors reduced not only blood pressure but other cardiovascular events (e.g., AMI, stroke, and death) in high-risk patients, including those with PAD, no specific class of antihypertensives are recommended over another for the treatment of hypertension for patients with PAD. Therefore, selection of drug therapy for hypertension should be made in accordance with the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC VII)[14] guidelines on the basis of comorbid disease states, drug costs and availability, drug allergies, or other possible limiting factors. For example, patients with concomitant Raynaud phenomenon may benefit from calcium channel blockers, while patients with documented CAD may receive a dual benefit by the selection of a β-blocker whereas patients with.[14,41,58] Hesitation to use β-blockers in patients with PAD without harm was recently supported with the publication of a review of six randomized controlled trials by Paravastu and colleagues.[59] The review concluded that there was no evidence of harm in the use of these agents for patients with PAD; however, β-blockers should be used with caution for patients with critical leg ischemia where acute lowering of blood pressure is contraindicated.[59] Dosing, monitoring guidelines and contraindications for specific agents used in the treatment of hypertension may be found in Chapter 19, Hypertension.

Hyperlipidemia

Although it has been shown that a reduction in lipid levels can reduce the progression of PAD and the severity of claudication, the current recommendations for the management of hyperlipidemia in PAD are based on only a few small studies and sub-hoc analyses from larger trials.[8,41,60–62] The Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III, or ATP III) considers PAD to be in the category of highest risk, or a coronary heart disease (CHD) risk equivalent. Therefore, it was recommended by the Expert Panel that levels of LDL be maintained at <100 mg/dL and non-high-density lipoprotein levels [total cholesterol minus high-density lipoprotein (HDL) cholesterol] at <130 mg/dL.[60] Results of clinical trials conducted since the time of this recommendation, specifically the Heart Protection Study (HPS)[62] and the Pravastatin or Atorvastatin Evaluation and Infection—Thrombolysis in Myocardial Infarction (PROVE IT)[63] trial, have lead many clinical experts to now recommend an LDL goal of <70 mg/dL for additional retardation of atherosclerotic plaque formation in persons considered to be at very high risk, including patients with PAD.[20] Regardless of the goal LDL chosen, initiation of patient therapeutic lifestyle changes (e.g., reduction in saturated fat, weight reduction, and increased physical activity) are vital to achieving these recommendations.[16,60] Unfortunately, in many cases, therapeutic lifestyle changes alone will not achieve the desired goals.

Several options are available for the initiation of drug therapy for LDL lowering for patients with PAD. Statins, bile acid sequestrants, and nicotinic acid are all effective treatment options. However, in most cases, statins are the preferred starting agent in this patient population.[24,42,60,62] As proven in the HPS, simvastatin demonstrated potent action not only in reducing LDL but also in providing a significant reduction in cardiovascular events overall as well (e.g., AMI, stroke, and death).[62] If an increase in HDL levels is also necessary, niacin should be considered alone or in combination with a statin without the fear of worsening glucose metabolism, as previously believed.[8,21,30,58,64] Dosing, monitoring guidelines, and contraindications for specific agents may be found in Chapter 28, Dyslipidemia.

Diabetes Mellitus

A metaanalysis of over 95,000 diabetic patients provided additional support for the accepted premise that glycemic control serves as a risk factor for CVD.[65] The analysis demonstrated an increasing risk of death from cardiovascular events as blood glucose concentrations increased, with the same relationship observed even at levels below the threshold of clinically defined diabetes mellitus. This relationship is just one illustration of the criticality of good glycemic control. Due to the high prevalence of PAD among diabetic patients, the American Diabetes Association recommends ABI screening for PAD in all diabetics older than 50 years.[66] Due to the presence of peripheral neuropathy, patients with diabetes may be less likely to experience or report symptoms of PAD, and the first sign may be as drastic as the appearance of a gangrenous foot ulcer. Therefore, although there is currently a lack of randomized controlled studies illustrating that the degree of glycemic control is predictive of the extent of PAD present, it is widely recommended that all patients with concomitant diabetes and PAD maintain good glycemic control, as evidenced by a hemoglobin A-1c level of <7%.[8,28,30,41,43,66,67] This recommendation was later supported by a prospective cohort study of 1,894 diabetic patients which demonstrated that patients

with poor glucose control (A-1c>7.5%) were 5 times more likely to develop IC and also to be hospitalized for PAD compared with those with a hemoglobin A-1c<6%.[68] Despite this, a study by Rehring and colleagues[69] of 365 patients with known PAD and concomitant diabetes showed that only 45.8% of these patients had a hemoglobin A-1c<7%. Oral antidiabetic agents, insulin regimens, as well as other pharmacologic and nonpharmacologic strategies to reduce the risk of complications associated with diabetes mellitus are discussed at length in Chapter 83, Diabetes Mellitus.

ANTIPLATELET DRUG THERAPY (TABLE 29–2)

Aspirin

6 By far, the most compelling evidence for the use of any pharmacologic agent in PAD can be found for aspirin (acetylsalicylic acid [ASA]). The Antithrombotic Trialists' Collaboration (ATC) conducted a metaanalysis of 195 randomized trials, composed of over 135,000 patients at high risk for occlusive arterial disease, and concluded that low-dose ASA (75 to 160 mg) and medium-dose ASA (160 to 325 mg/day) lead to a significant reduction in serious vascular events (12%) in "high-risk" patients, such as those with PAD.[70] The ATC also noted in this analysis that the risk of major extracranial bleed was similar between the low-dose and medium-dose regimens.

Tran and Anand[71] conducted a systematic review of the literature in an effort to summarize the best evidence for oral antiplatelet therapy for patients with cerebrovascular disease, CAD, and PAD. This review included 111 trials (42 of which included patients with PAD, n = 9,214) and concluded that patients with PAD should use ASA (160 to 325 mg/day) or clopidogrel (75 mg/day) when ASA is not tolerated or contraindicated.[71] This is in concordance with the recommendations of the Seventh American College of Chest Physicians (ACCP) Conference on Antithrombotic and Thrombolytic Therapy, which recommends lifelong ASA (75 to 325 mg/day) over clopidogrel, ticlopidine, and no antithrombotic therapy for patients with PAD.[72] Unfortunately, no data are currently available from large, clinical, randomized trials that ASA, or any other antiplatelet therapies, can actually prevent or delay the progression of PAD. [72]

Aspirin plus Dipyridamole Extended Release (Aggrenox)

The ATC also examined the use of dipyridamole extended release (Aggrenox) in combination with ASA in high-risk patients, such as those with PAD. The metaanalysis of 25 trials (which included more than 10,000 patients) concluded that the addition of dipyridamole to aspirin led to an additional reduction in serious vascular events over ASA alone (6%); however, this reduction was unable to reach statistical significance (P = 0.32).[70,71] It should also be taken into consideration that most of the reduction in nonfatal stroke in this analysis came from one trial, and these data are not replicated in the other studies.[70,73] The addition of dipyridamole to ASA may cause an increased risk of bleeding and gastrointestinal side effects when compared with placebo and should not be used with CAD.[73]

Clopidogrel (Plavix)

The ATC metaanalysis also reviewed the effectiveness of clopidogrel (Plavix) 75 mg/day in high risk patients, including those with PAD. The ATC concluded that although clopidogrel was able to reduce serious vascular events by 10%, this was significantly less than the reduction seen with ASA (12%, P = 0.03) described previously.[70] Included in this metaanalysis was the report from the Clopidogrel

TABLE 29-2 Pharmacotherapy Options for Patients with Peripheral Arterial Disease

Agent	Daily Dose (Oral)	Mechanism of Action (MOA)	Side Effects	Contraindications	Level of Evidence[b]
Aspirin	81–325 mg	Irreversibly inhibits prostaglandin cyclooxygenase in platelets, prevents formation of thromboxane A_2	Gastrointestinal upset and/or bleeding	Active bleeding; hemophilia; thrombocytopenia	With coronary or cerebrovascular (Grade 1A), without (Grade 1C+)
Dipyridamole ER (Aggrenox)	400 mg(+ aspirin 50 mg)	May act by inhibiting platelet aggregation (complete MOA unknown)	Angina; dyspnea; hypotension; headache; dizziness	Active bleeding; CAD ("coronary steal syndrome")	Recommendation for use not specified in report
Cilostazol (Pletal)[a]	100 mg BID	Phosphodiesterase inhibitor, suppresses platelet aggregation; direct artery vasodilator	Fever: infection; tachycardia	All CHF patients (decreased survival)	With IC (Grade 2A)
Clopidogrel (Plavix)	75 mg	Inhibits binding of ADP analogues to its platelet receptor causing irreversible inhibition of platelets	Chest pain; purpura generalized pain; rash	Active pathological bleeding (e.g., peptic ulcer, intracranial hemorrhage)	Recommend clopidogrel over no antiplatelet therapy (Grade 1C+)
Pentoxifylline (Trental)	1.2 g	Alters RBC flexibility; decreases platelet adhesion; reduces blood viscosity; decreases fibrinogen concentration	Dyspnea; nausea; vomiting; headache; dizziness	Recent retinal or cerebral hemorrhage; active bleeding	Not recommended in patients with IC (Grade 1B)
Ticlopidine (Ticlid)	500 mg	Inhibits binding of ADP analogues to its platelet receptor causing irreversible inhibition of platelets	Leukopenia; rash;thrombocytopenia; neutropenia; agranulocytosis; aplastic anemia	Active bleeding; hemophilia; thrombocytopenia	Clopidogrel recommended over ticlopidine (Grade 1C+)

Abbreviations: ER, extended-release; mg, milligrams; g, grams; BID, twice daily; ADP, adenosine 5'-diphosphate; RBC, red blood cell; CAD, coronary artery disease; CHF, congestive heart failure; IC, intermittent claudication.

[a]Cilostazol should be used in combination with antiplatelet therapy.

[b]Grades of recommendation for antithrombotic and thrombolytic therapy are part of the Seventh ACCP Conference on Antithrombotic and Thrombolytic Therapy.[87]

Data from references 5, 22, 30, 31, 70, 72, 76, 79, 88–91.

versus ASA in Patients at Risk of Ischemic Events (CAPRIE)5 trial, which had concluded that clopidogrel (75 mg daily) was more effective than ASA (325 mg daily) in preventing vascular events in high-risk patients. In comparison to the ASA therapy, the clopidogrel regimen resulted in an overall reduction in ischemic stroke, MI, or vascular death from 5.83% to 5.32% ($P = 0.043$). This difference was even more pronounced in the subgroup analysis of PAD patients, in which clopidogrel therapy led to a significant reduction of 4.86% versus 3.71% in the ASA group ($P = 0.0028$).[5,31,36] Although a generic clopidogrel product is now available, it not only remains significantly more expensive than ASA therapy, in drug costs, but clopidogrel also remains a by-prescription-only medication and thus requires a physician visit to obtain a prescription for the medication. For all these reasons, the current recommendations list clopidogrel as a first-line agent, but only in cases where ASA therapy is either not tolerated or contraindicated.[70]

Ticlopidine (Ticlid)

Although ticlopidine has the same mechanism of action as clopidogrel and possesses a similar molecular structure, the results of clinical trials among the two agents are strikingly different.[22] The Swedish Ticlopidine Multicenter Study (STIMS)[74] had determined that ticlopidine therapy (500 mg/day) was able to reduce total mortality in comparison with placebo for patients with IC ($P = 0.015$).[22,74,75] However, the once promising results seen with ticlopidine therapy have now been overshadowed by the severe hematologic side effects unique to this agent. Ticlopidine has a "black box" warning from the Food and Drug Administration (FDA) warning providers that use of this agent can cause neutropenia/agranulocytosis, thrombotic thrombocytopenic purpura, and aplastic anemia.[76] Other agents, namely clopidogrel, are now used instead of ticlopidine.[8,30,43]

INTERMITTENT CLAUDICATION (TABLE 29–2)

Cilostazol (Pletal)

7 In a head-to-head, randomized, placebo-controlled study in 698 patients with moderate-to-severe claudication, Dawson and colleagues[77] assigned patients to cilostazol (100 mg twice a day), pentoxifylline (400 mg 3 times a day), or placebo in an effort to improve maximal walking distance. After 24 weeks, the cilostazol group demonstrated a 54% mean increase in distance versus pentoxifylline, which demonstrated only a 30% mean increase ($P < 0.001$).[77] Similarly, a metaanalysis of 8 randomized, double-blind, placebo-controlled, parallel-design trials supported this conclusion with a reported increase in maximal walking distance and pain-free walking distance with cilostazol at doses of 50 mg and 100 mg twice-daily ($P < 0.05$ for all) over placebo.[78] Regrettably, improvement in walking distance has appeared to come with a price (in addition to the high drug cost); cilostazol has a "black box" warning from the FDA warning providers not to use this medication for patients with PAD and coexisting heart failure.[79] However, the Seventh ACCP Conference on Antithrombotic and Thrombolytic Therapy does suggest the use of this agent for patients with PAD are not candidates for surgical interventions to improve severe IC that persists even after implementation of appropriate exercise therapy and therapeutic lifestyle changes.[72]

Pentoxifylline (Trental)

Unlike cilostazol, pentoxifylline has produced results in clinical trials that are less promising, as illustrated by the randomized, placebo-controlled trial by Dawson and colleagues.[77] Not only did cilostazol outperform pentoxifylline in improvement in walking distance, the improvement seen with pentoxifylline was no different from placebo ($P = 0.82$).[77] This nonsignificant improvement in walking distance has been observed in other studies as well.[8,80] Meanwhile, other metaanalyses of pentoxifylline in comparison with placebo for the improvement of maximal walking distance have shown some minimal improvement over placebo, but the average effects were relatively small.[8,81–91] For these reasons, the Seventh ACCP Conference on Antithrombotic and Thrombolytic Therapy does not recommend the use of this agent.[72,87]

EVALUATION OF THERAPEUTIC OUTCOMES

It is vital that the patient be counseled on the evaluation measures that will be used to monitor the outcomes of therapeutic interventions for PAD. Various laboratory measurements will assess patient progress in glycemic control (e.g., hemoglobin A-1c) and lipid management (e.g., total cholesterol, LDL, HDL, and non-HDL cholesterol), while blood pressure checks in the clinic and patient home blood pressure monitoring can assess the effectiveness of antihypertensive therapy. Repeat exercise treadmill walking testing should be repeated at regular intervals (e.g., quarterly to biannually) to assess improvement or decline in walking duration and distance, as well as the time to pain onset while performing this activity. Repeat ABI measurements should be assessed at each patient visit to determine if there has been stabilization or progression of the disease process. Most importantly to many patients, simple concern and questioning about improvements to their daily quality of life will highlight your concern for their well-being and aid in an overall picture of the patient's general state of health.

CHAPTER 30

Use of Vasopressors and Inotropes in the Pharmacotherapy of Shock

ROBERT MACLAREN, MARIA I. RUDIS, AND JOSEPH F. DASTA

KEY CONCEPTS

1. Continuous hemodynamic monitoring with an arterial catheter or a central venous catheter capable of measuring mixed venous oxygen saturation (Svo_2) or central venous oxygen saturation ($Scvo_2$) should be used early and throughout the course of septic shock to assess intravascular fluid status and ventricular filling pressures, determine cardiac output (CO), and monitor arterial and venous oxygenation. They can be used for monitoring the response to drug therapy and guiding dosage titration.
2. Early goal-directed therapy with aggressive fluid resuscitation in the emergency department within the first 6 hours of presentation improves survival of patients with sepsis and septic shock.
3. Lactate production is increased under anaerobic conditions. Elevated serum lactate concentrations represent global perfusion abnormalities. Lactate may be used to assess repayment of oxygen to the tissues. Gastrointestinal tonometry and sublingual capnometry represent methods of assessing regional perfusion but are used infrequently.
4. Derangements in adrenergic receptor sensitivity or activity frequently result in resistance to catecholamine vasopressor and inotropic therapy in critically ill patients. These changes may be a function of endogenous catecholamine concentrations, dosage/duration of exposure to and type of exogenously administered vasopressors, stage of septic shock, preexisting illness, and other factors.
5. In refractory septic shock, rational use of vasopressor or inotropic agents should be guided by receptor activity, pharmacologic and pharmacokinetic characteristics, and regional and systemic hemodynamic effects of the drug and should be tailored to the patient's physiologic needs. Pharmacologically sound combinations of vasopressor and/or inotrope agents should be initiated early to optimize and facilitate rapid response.
6. Goals of therapy with vasopressors and inotropes should be predetermined and should optimize global and regional perfusion parameters (e.g., cardiac, renal, mesenteric, and periphery). This can be accomplished by continuous or intermittent measurements. Targeted goals should be central venous pressure (CVP) of 8–12 mm Hg (up to 15 mm Hg in mechanically ventilated patients, patients with preexisting left ventricular dysfunction, or patients with abdominal distension), mean arterial pressure (MAP) ≥65 mm Hg, and $Svo_2/Scvo_2$ ≥70%.
7. Dose titration and monitoring of vasopressor and inotropic therapy should be guided by the "best clinical response" while observing for and minimizing evidence of myocardial ischemia (e.g., tachydysrhythmias, electrocardiographic changes), renal (decreased glomerular filtration rate and/or urine production), splanchnic/gastric [low intramucosal pH, bowel ischemia], or peripheral (cold extremities) hypoperfusion, and worsening of partial pressure of arterial oxygen (Pao_2), pulmonary artery occlusive pressure, and other hemodynamic variables.
8. Much higher dosages of all vasopressors and inotropes than traditionally recommended are required to improve hemodynamic and oxygen-transport variables in patients with septic shock. Arbitrarily targeting vasopressor and inotrope therapy to supranormal values of global oxygen-transport variables cannot be recommended because of the lack of clear benefit and possible increased morbidity.
9. First-line therapy of septic shock is aggressive volume resuscitation with crystalloid or colloid types of fluids. Dopamine or norepinephrine typically is used as the initial vasopressor agent for hemodynamic support. Dopamine is limited by its ability to increase CO and complications of tachycardia, tachydysrhythmias, increase in pulmonary artery occlusive pressure, and decrease in splanchnic oxygen use. Low-dose dopamine should not be used to prevent renal failure. Norepinephrine may achieve greater hemodynamic response than dopamine and is less likely to cause tachydysrhythmias and a decrease in splanchnic oxygen utilization.
10. Phenylephrine may be a particularly useful alternative in patients who cannot tolerate tachycardia or tachydysrhythmia associated with the use of other agents. Its effects on cardiac performance and splanchnic oxygen utilization are variable.
11. Epinephrine appears to be effective as a single agent and as an add-on agent. It is particularly useful in the young, in patients with otherwise healthy myocardium, and potentially in patients when used early in the course of treatment. However, because epinephrine causes a significant increase in lactate and worsening of splanchnic oxygen utilization, it is not the agent of first choice in patients with septic shock. It should be used cautiously in patients with a history of coronary artery disease or underlying cardiac disturbances.
12. Dobutamine may be used as adjunctive therapy for its inotropic effect. It enhances CO and may increase $Svo_2/Scvo_2$. Concurrent vasopressor therapy is needed because dobutamine causes vasodilation. Dobutamine therapy may be limited by tachycardia and dysrhythmias.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

13 Therapy with vasopressors and inotropes is continued until the myocardial depression and vascular hyporesponsiveness of septic shock improve, usually measured in hours to days. Discontinuation of vasopressor or inotropic therapy should be executed slowly; therapy should be "weaned" to avoid a precipitous worsening in regional and systemic hemodynamics.

14 Vasopressin produces vasoconstriction independent of adrenergic receptors and reduces the dosages of catecholamine vasopressors. Replacement dosages of vasopressin (0.01–0.04 units/min) can be considered in patients with septic shock refractory to catecholamine vasopressors despite adequate fluid resuscitation. Dosage rates should not be titrated upward. Vasopressin may enhance urine production but it may worsen splanchnic and peripheral perfusion. Given the current data, corticosteroids can be administered to patients with septic shock refractory to vasopressors or when adrenal insufficiency is present. Side effects of short-term corticosteroids are minimal.

Shock is an acute, generalized state of inadequate perfusion of critical organs that can produce serious pathophysiologic consequences, including death, when therapy is not optimal. Shock is defined as systolic blood pressure <90 mm Hg or reduction of at least 40 mm Hg from baseline with perfusion abnormalities despite adequate fluid resuscitation.[1] Previously, mortality from septic or cardiogenic shock exceeded 70% but now ranges between 30% to 50%.[2–5] This chapter reviews the theory and current status of hemodynamic monitoring and presents an update on the optimal use of inotropes and vasopressor drugs in shock states, specifically septic shock.[6–19]

Hemodynamic and perfusion monitoring can be categorized into two broad areas: global and regional monitoring. Global parameters, such as systemic blood pressure and pulse oximetry, assess perfusion and oxygen utilization of the entire body. Regional monitoring techniques, such as tonometry, focus on oxygen delivery and subsequent changes in metabolism of individual organs and tissues. Normal values for commonly monitored parameters are listed in Table 30–1. Evidence-based goals of therapy are listed in Table 30–2.[6–19] The adequacy of regional perfusion can be assessed

TABLE 30-1 Hemodynamic and Oxygen-Transport Monitoring Parameters

Parameter	Normal Value[a]
Blood pressure (systolic/diastolic)	100–130/70–85 mm Hg
Mean arterial pressure (MAP)	80–100 mm Hg
Pulmonary artery pressure (PAP)	25/10 mm Hg
Mean pulmonary artery pressure (MPAP)	12–15 mm Hg
Central venous pressure (CVP)	8–12 mm Hg
Pulmonary artery occlusive pressure (PAOP)	12–15 mm Hg
Heart rate (HR)	60–80 beats/min
Cardiac output (CO)	4–7 L/min
Cardiac index (CI)	2.8–3.6 L/min/m^2
Stroke volume index (SVI)	30–50 mL/m^2
Systemic vascular resistance index (SVRI)	1,300–2,100 dyne • s/m^2 • cm^5
Pulmonary vascular resistance index (PVRI)	45–225 dyne • s/m^2 • cm^5
Arterial oxygen saturation (Sao_2)	97% (range, 95%–100%)
Mixed venous oxygen saturation (Svo_2)	70%–75%
Arterial oxygen content (Cao_2)	20.1 vol% (range, 19–21)
Venous oxygen content (Cvo_2)	15.5 vol% (range, 11.5–16.5)
Oxygen content difference ($C[a–v]O_2$)	5 vol% (range, 4–6)
Oxygen consumption index (VO_2)	131 mL/min/m^2 (range, 100–180)
Oxygen delivery index (Do_2)	578 mL/min/m^2 (range, 370–730)
Oxygen extraction ratio (O_2ER)	25% (range, 22–30)
Intramucosal pH (pHi)	7.40 (range, 7.35–7.45)
Index (I)	Parameter indexed to body surface area

[a]Normal values may not be the same as values needed to optimize the management of a critically ill patient.

TABLE 30-2 Evidence-Based Treatment Recommendations for Management of Severe Sepsis or Septic Shock

Recommendations	Grade
In patients requiring vasopressors, an arterial catheter should be placed as soon as practical to monitor blood pressure.	1D
Begin resuscitation immediately in patients with hypotension or elevated serum lactate.	1C
Goals of resuscitation should include (1) CVP 8–12 mm Hg,[a] (2) MAP ≥65 mm Hg, (3) urine production ≥0.5 mL/kg/h, and (4) Svo_2 or $Scvo_2$ ≥70%.	1C
If Svo_2 or $Scvo_2$ ≥70% not achieved, consider the following: (1) further fluid administration, (2) transfuse packed red blood cells to hematocrit ≥30%, or (3) dobutamine infusion ≤20 mcg/kg/min.	2C
Fluid resuscitate using crystalloids or colloids.	1B
Use a fluid challenge technique to determine associated hemodynamic improvement. Administer 1000 mL of crystalloid or 300–500 mL of colloid over 30 minutes. More rapid and larger volumes may be required. Rate of fluid administration should be reduced if cardiac filling pressures increase without concurrent improvement.	1D
Use vasopressors to maintain MAP ≥65 mm Hg.	1C
Either dopamine or norepinephrine centrally administered are the initial vasopressors of choice.	1C
Epinephrine, phenylephrine, or vasopressin should not be administered as the initial vasopressor. Vasopressin 0.03 units/min may be subsequently added to norepinephrine with an anticipation of an effect equivalent to norepinephrine alone.	2C
Use epinephrine as the first alternative agent when blood pressure is poorly responsive to dopamine or norepinephrine.	2B
Do not use low-dose dopamine for renal protection.	1A
Use dobutamine in patients with myocardial dysfunction as supported by elevated cardiac filling pressures and low CO.	1C
Do not increase cardiac output to predetermined supranormal indices.	1B
Consider intravenous hydrocortisone when hypotension remains poorly responsive to adequate fluid resuscitation and vasopressors.	2C
ACTH stimulation test is not recommended to identify the subset of patients who should receive hydrocortisone.	2B
Hydrocortisone is the preferred corticosteroid.	2B
Hydrocortisone dose should be ≤300 mg/day.	1A
Corticosteroid therapy may be weaned once vasopressors are no longer required.	2D
Do not use corticosteroids to treat sepsis in the absence of shock unless the patient's endocrine or corticosteroid history warrants it.	1D

[a]A higher target CVP of 12–15 mm Hg may be required in the presence of mechanical ventilation or preexisting left ventricular dysfunction or abdominal distension.

ACTH, adrenocorticotropic hormone; CO, cardiac output; CVP, central venous pressure; Do_2, oxygen delivery; MAP, mean arterial pressure; $Scvo_2$, central-venous oxygen saturation; Svo_2, mixed venous oxygen saturation. Level of recommendations: 1, a strong recommendation indicating that the intervention's desirable effects clearly outweigh its undesirable effects; 2, a weak recommendation indicating that the tradeoff between desirable and undesirable effects is less clear. Quality of evidence: A, supported by a randomized control trial; B, supported by a downgraded randomized control trial or upgraded observational studies; C, supported by observational studies; D, supported by case series or expert opinion.

Based on data from references 6–19.

by indices of specific organ perfusion.[7,16–21] These measurements include coagulation abnormalities (disseminated intravascular coagulation), altered renal function with reduced urine production or increased serum concentrations of blood urea nitrogen and creatinine, altered hepatic parenchymal function with increased serum concentrations of transaminases and bilirubin, altered gastrointestinal perfusion manifested by ileus and diminished bowel sounds, cardiac ischemia with elevated troponin levels and electrocardiographic changes, and altered sensorium. Although none of these indices alone is a reliable indicator of adequate resuscitation, they offer immediate detection and may be prognostic of recovery when combined and defined at the level of organ function. As a result, these indices are frequently used as surrogate endpoints for the goals of resuscitation.[22] While it is assumed that normalization of these parameters infers benefit, the clinician must first treat the patient rather than relying solely on data from continuous monitoring to guide therapy.[22]

GLOBAL PERFUSION MONITORING

ARTERIAL BLOOD PRESSURE MEASUREMENT

Mean arterial blood pressure (MAP) is the product of cardiac output (CO) and systemic vascular resistance (SVR). Conditions that may lower blood pressure in critically ill patients include cardiac failure (etiology may be myocardial infarction, arrhythmia, acute heart failure, or valvular disease) and hypovolemia (etiology may be hemorrhage, intractable diarrhea, or heat stroke) by lowering CO and vasodilation (etiology may be sepsis, drugs, anaphylaxis, acute hepatic failure, or neurotrauma) by lowering SVR. Arterial blood pressure is the end point of therapy; however, restoration of adequate perfusion pressure is the primary criterion of effectiveness.[6–21] Profound hypotension (MAP <50 mm Hg) is associated with a pressure-dependent decrease in coronary and cerebral blood flow and may rapidly produce myocardial and cerebral ischemia. Arterial blood pressure can be determined by noninvasive and invasive methods. All noninvasive blood pressure monitoring techniques depend on the use of an occluding cuff. Systolic and diastolic blood pressures are further determined by auscultation, palpation (systolic pressure only), oscillometry, or Doppler technique (systolic pressures are most reliable). Auscultation is the most commonly used method outside the intensive care unit (ICU). Its use, however, is limited in patients with hypovolemia, hypothermia, or cardiogenic shock when pulses or Korotkoff sounds may be difficult to hear. Similar constraints exist for the palpation and oscillometric methods. However, oscillometry is preferred in edematous patients. Oscillometry measures blood pressure by sensing arterial blood pressure changes, or oscillations, against an inflated cuff. Rapid changes in oscillation amplitude correspond to systolic and diastolic pressure. It is the only noninvasive method to measure MAP even in low-flow states and lends itself to automatic cycling and serial measurements (every 1–3 minutes) that do not require operator intervention, a key component in ICU monitoring. The use of narrow cuffs or cuffs applied too loosely can result in falsely high readings, whereas wide cuffs may produce falsely low readings. Fingertip devices offer another avenue for continuous indirect blood pressure measurement, but their accuracy in ICU patients may be significantly diminished by concurrent administration of vasoactive drugs.

1 The use of invasive arterial catheters makes possible the continuous measurement of MAP as well as procurement of blood samples for blood gas monitoring. The radial artery is the most commonly used vessel, but the dorsalis pedis, femoral, brachial, and axillary arteries and the umbilical artery in the newborn also can be accessed. This method of blood pressure monitoring is the standard technique used in the ICU against which all other methods are compared. Major complications of peripheral artery catheterization include infection and distal ischemia. Acute distal ischemia and catheter-related bacteremia occur in <1% of catheter insertions. This translates to 2.9% of bloodstream infections per 1,000 catheter-days.[23] Ischemia is most common in patients with multiple or prolonged arterial cannulations, hypertension, or vasopressor therapy.[8] Invasive techniques are labor intensive, require aseptic techniques, and offer potential sources of equipment errors, such as length and quality of tubing, air bubbles, stopcocks, thrombus formation, tube kinking, and transducer placement. Hypertension, advanced age, and atherosclerosis also may affect the accuracy of invasive blood pressure readings.[19]

CENTRAL VENOUS CATHETER

1 The central venous catheter is used to measure the central venous pressure (CVP), to obtain venous blood gas samples, and to administer drugs or fluids directly to the central circulation. A triple-lumen catheter frequently is used, whereby drugs with known incompatibility can be administered. Blood volume, venous wall compliance, right-sided cardiac function, intraabdominal and intrathoracic pressures, and vasopressor therapy affect CVP. The CVP is not a reliable estimate of blood volume but can be used to qualitatively assess blood volume changes in patients during the early phases of fluid resuscitation.[6–8] The goal of fluid administration is to maintain the CVP at 8 to 12 mm Hg, but values of 15 mm Hg may be targeted in mechanically ventilated patients or patients with abdominal distension or preexisting ventricular dysfunction.[6–8] Sustained elevated pressures may be indicative of fluid overloading. Few data support the use of continuous CVP monitoring in the ICU. However, CVP monitoring of fluid therapy during resuscitation of septic shock is associated with reduced mortality.[9]

PULMONARY ARTERY CATHETER

1 Pulmonary artery catheterization provides multiple cardiovascular parameters, including CVP, pulmonary artery pressure, pulmonary artery occlusive pressures (PAOP), CO, SVR, and the mixed-venous oxygen saturation (Svo_2).[24] Ideally, the pulmonary artery catheter should be positioned fluoroscopically; however, satisfactory placement also may be obtained by observing pulmonary artery pressure readings and electrocardiographic waveforms during catheter advancement. Proper positioning in the lower lung (zone 3) is essential to measure PAOP and to prevent distal pulmonary artery collapse. Inflation of the balloon at the catheter tip occludes the pulmonary artery, isolates the distal catheter tip from the right side of the heart, and allows the user to measure the PAOP, an approximate measure of the left ventricular end-diastolic volume and a major determinant of left ventricular preload. Poor wedging may be caused by catheter migration, patient movement, mechanical ventilation, or eccentric balloon inflation. Pulmonary artery catheters equipped with a distal thermistor also allow measurement of CO by thermodilution. Rapid injection of saline or dextrose solutions via the right atrial port allows complete mixing of blood with the injectate, and the resulting change in blood temperature is measured in the pulmonary artery. From the temperature change, the patient's CO can be calculated. Newer pulmonary artery catheters contain a temperature coil that intermittently warms the blood in the right ventricle for near-continuous CO measurement. Significant tricuspid regurgitation, an intracardiac shunt, and significant positive end-expiratory pressure decrease the validity of CO measurements. The most common complications of pulmonary artery catheterization include mural thrombus formation (14%–91%), transient ventricular tachydysrhythmias (11%–63%), pulmonary infarction (1%–7%), pulmonary artery rupture (0.06%–2.0%), and sepsis (0.3%–0.5%).[25]

Most pulmonary artery catheters are heparin bonded, and the relative risk (RR) of infection is 2.6 per 1,000 patient-days, similar to the risk with central venous catheters of 2.3 per 1,000 patient-days.[23] Controversy surrounds the utility and safety of the pulmonary artery catheter, including issues surrounding correct placement and impact of the device on patient outcome. Recent studies failed to demonstrate beneficial outcomes with the use of the pulmonary artery catheter.[26] The most recent guidelines suggest careful evaluation of the indications and the risk of placing a pulmonary artery catheter for resuscitation of critically ill patients.[27]

1 The optimal PAOP needs to be individualized for each patient. Administering a fluid bolus followed by simultaneous PAOP and CO measurements with the goal of increasing the PAOP until CO does not change can be accomplished and is based on Starling's law of the heart. However, clinical experience suggests that most patients have an optimal response to PAOP values in the range from 12 to 15 mm Hg.

CLINICAL CONTROVERSY: CVP VS PAOP

Limited data are available comparing the use of CVP and PAOP for guiding therapy in patients with shock. The results of recent studies of critically ill patients suggest CVP and PAOP are equivalent in terms of clinical outcomes, including mortality.[28] Therefore, a pulmonary artery catheter should be inserted when hemodynamic data are needed that cannot be obtained from a central venous catheter or when the validity of measurements from the central venous catheter is questionable.

1 Other methods used to assess CO include carbon dioxide (CO_2) partial rebreathing and esophageal Doppler.[22,29] The CO_2 partial rebreathing technique compares end-tidal CO_2 partial pressure obtained during a nonrebreathing period with that obtained during a subsequent rebreathing period. The ratio of change in end-tidal CO_2 and CO_2 elimination estimates CO but must be corrected for blood shunting. Poor to acceptable agreement exists between this method and the thermodilution method of assessing CO in critically ill patients. Also, low minute ventilation, a high shunt fraction, or a high cardiac output produce inaccurate results. The esophageal Doppler technique measures flow velocity in the descending aorta by means of a Doppler transducer. CO is calculated based on the diameter of the aorta, the distribution of CO to the aorta, and the flow velocity of blood in the aorta. The CO reported by this method correlates with therapeutic interventions and demonstrates excellent agreement with the pulmonary artery catheter. Unfortunately, this method is technologically difficult and may not produce reliable measurements over time.

OXYGEN TENSION AND SATURATION MONITORING

Partial pressure of arterial oxygen (Pao_2) and arterial oxygen saturation (Sao_2) can be measured subjectively by assessing capillary refill or invasively by obtaining an arterial blood sample. Arterial blood gases measured by conventional arterial sampling are considered standard, but their accuracy and usefulness are affected by poor sampling techniques, transportation and analysis delays, analyzer accuracy, sample cellular metabolism, and inability to trend results. Indwelling fiberoptic and electrochemical systems that allow continuous monitoring and trend analyses of blood pH, Pao_2, and partial pressure of arterial carbon dioxide ($Paco_2$) while decreasing patient blood loss from less frequent sampling are in development.

1 Mixed venous oxygen saturation (Svo_2) depends on CO, oxygen demand, hemoglobin, and Sao_2. It can be measured in patients using a pulmonary artery catheter. Initially, critically ill septic patients may present with a low Svo_2 value (<70%), indicating high extraction of oxygen by tissues and lack of adequate oxygen delivery (Do_2, or Do_2I, indexed to body surface area) to tissues. In patients with sepsis and other conditions who present with a low Svo_2 value, rapid intervention should be undertaken to increase Do_2 to tissues, with the goal of obtaining Svo_2 ≥70%.[30,31] The length of time Svo_2 is <70% is associated with mortality.[32] As sepsis worsens, however, Svo_2 may be ≥70%. This occurs because extraction of oxygen in the arteriolar beds is hampered and is indicative of poor outcome.

1 Central venous oxygen saturation ($Scvo_2$) is a less invasive measure of venous oxygen saturation because the catheter is placed at the junction of the inferior and superior venae cavae rather than at the pulmonary artery.[17–21] It is as accurate as Svo_2 but provides slightly higher normal values. Although controversial, many clinicians use these measurements interchangeably. Concentrations of $Scvo_2$ <70% reliably indicate inadequate oxygenation in shock states and detect subclinical ("cryptic") shock much earlier than hypotension. Targeting fluid and hemodynamic resuscitation to achieve $Scvo_2$ ≥70% is a sensitive indicator and measure of the extent of global tissue hypoxia, a determinant of the adequacy of hemodynamic resuscitation, and is associated with improved survival in patients with sepsis and septic shock.[17–21]

OXYGEN DELIVERY AND CONSUMPTION

Tissue oxygen debt is indicative of organ damage in critical illness. In normal individuals, oxygen consumption (Vo_2 or Vo_2I, indexed to body surface area) depends on Do_2 (or Do_2I) up to a certain critical level (Vo_2 flow dependency). At this point, tissue oxygen requirements apparently are satisfied, and further increases in Do_2 will not alter Vo_2 (Vo_2 flow independency). Although animal models of sepsis substantiate this relationship, studies in critically ill humans show a continuous, pathologic dependence relationship of Vo_2 with Do_2.[17–21,31] The Vo_2/Do_2 ratio, or oxygen extraction ratio (O_2ER), can be used to assess adequacy of perfusion and metabolic response.[17–21,31] Maintaining the oxygen extraction ratio (O_2ER) at <25% without a changing Vo_2 may be helpful in maintaining or improving the body's reserve in meeting the oxygen demands.[17–21,31] However, low Vo_2 and O_2ER values are indicative of poor oxygen utilization and lead to greater mortality. Patients who are able to increase Vo_2 when Do_2 is increased show improved survival. This finding became the basis for targeting supranormal Do_2 and Vo_2 values in the treatment of ICU patients.[9] However, a meta-analysis of randomized clinical trials involving 1,016 adult ICU patients failed to show that achievement of this goal improved mortality.[33] This may have been due in part to the heterogeneous nature of the ICU patients studied and therapies provided, lack of study blinding, crossover patients (control patients who achieve supranormal Do_2 and Vo_2 values by themselves), or lack of adequate control of cointerventions. The debate continues in more homogeneous patient populations. For example, in high-risk surgical patients, supranormal DO_2 values decrease mortality except in the subgroup of patients exceeding 75 years of age in whom achieving Do_2I >600 $mL/m^2/min$ show mixed mortality results.[31,33]

A review of alternative potential mechanisms of beneficial effect of supranormal Do_2 suggests that catecholamines exert antiinflammatory actions by modulating cytokine response.[34] In general, catecholamines inhibit the production of inflammatory cytokines (e.g., interleukin [IL]-6, tumor necrosis factor [TNF]-α) and may enhance synthesis of antiinflammatory cytokine (e.g., IL-4 and IL-10). The actions of epinephrine on these cytokines are blocked by propranolol and thus are mediated by adrenergic β-receptors.

Another problem with therapy directed to achieve supranormal oxygen transport values is that the apparent linear relationship between DO_2 and VO_2 has been questioned because both share variables, and this *mathematical coupling* can produce artifactual relationships between variables.[17–21] The DO_2 and VO_2 indexed parameters are calculated as follows:

$$Do_2 = CI \times Cao_2$$

$$Vo_2 = CI \times (Cao_2 - Cvo_2),$$

where CI = cardiac index, Cao_2 = arterial oxygen content determined by hemoglobin concentration and Sao_2, and Cvo_2 = mixed venous oxygen content determined by hemoglobin concentration and Svo_2.

However, variable relationships between Do_2 and Vo_2 are observed when Vo_2 is measured independently by indirect calorimetry. Therefore, a linear relationship between Do_2 and Vo_2 may be the result of mathematical coupling or flow-dependent Vo_2. Currently available data do not support the concept that patient outcome or survival is improved by treatment measures directed toward achieving supranormal Do_2 and Vo_2 values.[33] In fact, a consensus conference concluded that although pulmonary artery catheterization is useful for guiding therapy, routinely increasing cardiac index to predetermined supranormal values does not improve outcome.[6] Furthermore, achievement of a supranormal Do_2 does not ensure parallel improvements in regional organ blood flow and oxygenation. One approach that may decrease the effect of mathematical coupling and provide individualized therapy may lie in titrated therapy, with sequential measurements of Do_2 and Vo_2 to achieve Vo_2 flow independency along with normalization of blood lactate and hemodynamic parameters.

2 The most recent data regarding goal-directed therapy in the hemodynamic support of sepsis relates to the importance of achieving predetermined parameters early in the management of sepsis.[35] In a meta-analysis of early (defined as 8–12 hours postoperatively or before the development of organ failure) versus late (defined as after the onset of organ failure) resuscitative efforts in patients stratified according to severity of illness (determined by control group mortality >20% [12 studies] or <15% [9 studies]) and targeting supranormal oxygen-transport variables, the data suggest that timing of resuscitation matters.[35] Early goal-directed therapy reduced mortality and the development of organ failure in patients who were more severely ill and when therapeutic interventions produced differences in Do_2. Moreover, outcome was not improved significantly in less severely ill patients (control group mortality <15% and normal Do_2 values as goals) or when therapy did not improve Do_2.

2 6 More important than achieving supranormal Do_2 is the rapid initiation of therapy. In a prospective, randomized controlled trial, Rivers et al. demonstrated a significant reduction in mortality (30.5% vs 46.5%; P <0.001) in patients with severe sepsis and septic shock randomized to receive therapy based on goal-directed hemodynamic end points that were achieved within 6 hours of hospital presentation.[30] They used a strategy of serial administering (1) fluids rapidly to achieve CVP 8–12 mm Hg, (2) vasopressor agents to achieve MAP at least 65 mm Hg, (3) red blood cell transfusion to maintain hematocrit ≥30%, and (4) dobutamine to achieve $Scvo_2$ ≥70%. This approach demonstrates the benefits of initiating therapy early in the course of sepsis and directs therapy toward clearly defined goals in a consistent manner. The results of several evaluations of protocols or order sets designed to achieve the hemodynamic end points of early goal-directed therapy show that implementation is easily accomplished, cost is reduced, and patient outcomes, including survival, are improved.[36–41] A recent meta-analysis of nine studies showed reduced mortality when quantitative resuscitation goals are used to guide therapy (odds ratio [OR] 0.64; 95% confidence interval [CI] 0.43–0.96; P = 0.03).[42] Therefore, healthcare facilities should implement strategies to achieve early goal-directed therapy using the predefined hemodynamic variables of the study by Rivers et al.[30]

CLINICAL CONTROVERSY: GOALS OF EARLY GOAL-DIRECTED THERAPY

The results of studies cannot delineate which end point or combination of end points was most beneficial with respect to early goal-directed therapy. These studies also offer limited information about specific interventions to achieve the predefined goals. In addition, whether these goals must be maintained after resuscitation is unknown. Several studies are ongoing to address some of these issues.

BLOOD LACTATE

3 Lactate is a metabolic product of pyruvate. Its production is increased under anaerobic conditions, such as may occur during shock. Blood lactate concentrations are used as a diagnostic and prognostic tool in sepsis; they also are used to measure the repayment of oxygen debt to tissues.[17–21,31] It is a useful tool in combination with Do_2 and Vo_2 because these measures change independently of one another. Serial lactate concentrations may show better correlation with outcome than oxygen transport parameters and may be superior to hemodynamic markers in determining adequacy of restoration of systemic oxygenation.[17–21,31] However, several caveats guide the use of lactate concentrations in septic patients. First, lactate may accumulate in patients with other conditions, such as significant hepatic dysfunction or acute respiratory distress syndrome, who are not in shock. Second, both well-perfused and poorly perfused tissues contribute to arterial and mixed venous lactate concentrations and therefore are not reflective of regional perfusion. Third, although increased lactate concentrations have been correlated with increased mortality, the utility of blood lactate measurements in guiding therapy has not been clearly demonstrated. Fourth, elevated lactate concentrations may result from cellular metabolic failure rather than global hypoperfusion in shock. Serial blood lactate measurements are more useful than single isolated measurements and continuously elevated concentrations are predictive of morbidity and mortality.

REGIONAL PERFUSION MONITORING

GASTROINTESTINAL TONOMETRY

Blood pressures, CO, blood lactate, and global oxygen homeostasis parameters do not offer information about the function of individual organs. Organ-specific hypoxia may be evident by coagulopathy as indicated by thrombocytopenia (platelet count <100,000/L and/or prolonged clotting times [international normalized ratio >1.5 or activated partial thromboplastin time at least 1.5-fold the upper limit of normal]), impaired renal function with urine production <0.5 mL/kg/h and/or increased serum concentrations of blood urea nitrogen and creatinine, altered hepatic function with substantially increased serum concentrations of transaminases and bilirubin, altered gastrointestinal perfusion manifested by ileus and diminished bowel sounds, cardiac ischemia with elevated troponin levels and electrocardiogram changes, and altered sensorium.[7,22] Objective measurement of regional perfusion to detect inadequate tissue oxygenation has focused on the mesenteric/splanchnic circulation, which is sensitive to changes in blood flow and oxygenation for

several reasons.[17–21,43,44] First, the normally large majority of blood flow to the gut mucosa is redistributed toward the serosa and muscularis. Second, the gut may have a higher critical Do_2 threshold than other organs. Third, the tip of the villus has a countercurrent oxygen-exchange mechanism, rendering it highly sensitive to alterations in regional blood flow and oxygenation.

3 Gastric tonometry measures gut luminal partial pressure of carbon dioxide (Pco_2) at equilibrium by placing a saline- or air-filled gas-permeable balloon in the gastric lumen. Assuming that carbon dioxide (Co_2) permeates freely among tissues and that the arterial bicarbonate (Hco_3^-) concentration is equal to that of the gut mucosa, the intramucosal pH (pHi) may be calculated using the Henderson-Hasselbalch equation:

$$pHi = 6.1 \log (HCO_3^-) 0.03 \times Pco_2$$

Increases in mucosal Pco_2 and calculated decreases in pHi are associated with mucosal hypoperfusion and perhaps increased mortality.[17–21,43,44] Calculation of pHi can be confounded by increases in luminal Pco_2, such as may occur when buffering antacids are used. Histamine$_2$-receptor antagonists or proton pump inhibitors can be used instead. The presence of respiratory acid–base disorders; systemic bicarbonate administration; arterial blood gas measurement errors; or enteral feeding products, blood, or stool in the gut may confound pHi determinations. As a result, the change in gastric mucosal Pco_2 may be more accurate than pHi. Furthermore, because mucosal Pco_2 is influenced by arterial Pco_2, the mucosal–arterial Pco_2 difference (Pco_2 gap) likely is the optimal measurement.[17–21,43,44] Gastric tonometry can be performed using either a saline- or air-filled balloon. The time delay (30 minutes) associated with equilibration of saline inside the balloon makes this method impractical for monitoring of resuscitation and inconvenient for routine bedside monitoring. An air-filled balloon requires a shorter equilibrium time, is simpler to use, and is equally accurate. However, the clinical utility of gastric tonometry remains uncertain. Clinical trials of pHi-directed therapy do not show that it aids resuscitation when other goals are concomitantly targeted. Gastric tonometry, in general, inconsistently predicts mortality.

3 Evidence suggests that the most proximal part of the gastrointestinal tract, the sublingual mucosa, may be an acceptable location for monitoring regional perfusion and Pco_2.[17–21,43,44] Unlike gastrointestinal circulation, limited intra- and interpatient variability exists in the microvasculature and only few arterioles are available for assessment. Sublingual capnometry is noninvasive, is not technically complex, and provides results within minutes. The device consists of a disposable sublingual carbon dioxide pressure ($Pslco_2$) sensor, a fiberoptic cable that connects the disposable sensor to a blood gas analyzer, and a blood gas monitoring instrument. Small studies of critically ill patients with and without sepsis and septic shock show that the $Pslco_2$ and the sublingual-to-arterial Pco_2 gap correlate better with the enhancement of Do_2 with dobutamine than the mucosal Pco_2 and the mucosal-to-arterial Pco_2 gap.[17–21,43,44] The initial sublingual-to-arterial Pco_2 gap is a better predictor of mortality. These pilot studies must be expanded before this technology becomes part of routine practice, but it offers the possibility of noninvasive measurement of regional perfusion. Of note, some institutions have incorporated the $Pslco_2$ into their algorithms of early goal-directed therapy in an effort to provide additional information about the effectiveness of therapies during resuscitation.

MYOCARDIAL DYSFUNCTION

1 Although loss of vascular tone is the hallmark of septic shock, myocardial dysfunction characterized by transient impairment of contractility is a recognized complication.[45,46] The range of left ventricular ejection fraction (LVEF) upon presentation is wide, but approximately 35% of patients with septic shock have left ventricular hypokinesis (mean ejection fraction 38% ± 17%) and low CO.[45,46] Because LVEF also is affected by preload and afterload, the low SVR of septic shock may mask depressed myocardial contractility that may be revealed upon restoration of MAP by administration of fluid and vasopressors. Therefore, CO may not reflect the extent of myocardial dysfunction. While it requires technical and interpretive training, echocardiography is a relatively simple method of assessing cardiac function.[47,48] It can assess chamber size, ventricular contractility, valve function, and blood flow. Patients with tissue hypoxia or a hyper-contractile left ventricle may benefit from fluid administration or vasopressor therapy; whereas, patients with poor left ventricular function may require inotropic intervention. Like sublingual capnometry, some institutions use echocardiography to direct resuscitation therapies.[48]

Cardiac troponin release in septic patients occurs in the absence of flow-limiting disease, likely due to a loss in membrane integrity with subsequent leakage or microvascular thrombosis. Elevation of cardiac troponin concentrations in patients with sepsis indicates left ventricular dysfunction and portends a poor prognosis.[45,46] Troponin concentrations also correlate with the duration of hypotension and the intensity of vasopressor therapy. Early recognition of myocardial dysfunction is crucial for administration of appropriate therapy. In the absence of other mechanisms for assessing cardiac function, echocardiographic findings and troponin concentrations may help guide and monitor therapy. Whereas cardiac troponins may be integrated into the monitoring of myocardial dysfunction to identify patients requiring aggressive therapy, natriuretic peptides show variable correlation with LVEF and should not be routinely monitored.[45,46]

VASOPRESSORS AND INOTROPES

6 Vasopressors and inotropes in patients with septic shock are required when volume resuscitation fails to maintain adequate blood pressure (MAP ≥65 mm Hg) and organs and tissues remain hypoperfused despite optimizing CVP to 8 to 12 mm Hg or PAOP to 12 to 15 mm Hg.[7] However, vasopressors may be needed temporarily to treat life-threatening hypotension when filling pressures are inadequate despite aggressive fluid resuscitation. Inotropes are frequently used to optimize cardiac function in cases of cardiogenic shock. The clinician must decide on the choice of agent, therapeutic end points, and safe and effective doses of vasopressors and inotropes to be used. This section reviews adrenergic receptor pharmacology, exogenous catecholamine use, and alterations in receptor function in critically ill patients. It also provides guidelines for the clinical use of adrenergic agents, optimization of pharmacotherapeutic outcomes, and minimization of adverse effects in critically ill patients with septic shock. Therapies of hypovolemic shock and cardiogenic shock are discussed in other chapters.

Of note, agents other than catecholamines have been used as inotropes and vasopressors in shock states. They include phosphodiesterase III inhibitors, naloxone, nitric oxide (NO) synthase (NOS) inhibitors, and calcium sensitizers. This chapter focuses on catecholamines. Vasopressin and corticosteroids, as they relate to septic shock, also are emphasized because they have pharmacologic interactions with catecholamines, possess hemodynamic effects, and are frequently used.

CATECHOLAMINE RECEPTOR PHARMACOLOGY

5 Comparative receptor activities of endogenous and exogenously administered catecholamines is summarized in Table 30–3.[6–19,49–53] Endogenous catecholamines are responsible for regulation of

TABLE 30-3 Adrenergic, Dopaminergic, and Vasopressin Receptor Pharmacology and Organ Distribution

Effector Organ	Receptor Subtype	Physiologic Response
Heart		
Sinoatrial node	β_1, β_2	Increased heart rate
Atria	β_1, β_2	Increased contractility Increased conduction velocity
Atrioventricular node	β_1, β_2	Increased automaticity Increased conduction velocity
His-Purkinje system	β_1, β_2	Increased automaticity Increased conduction velocity
Ventricles	β_1, β_2	Increased contractility Increased conduction velocity Increased automaticity Increased rate idioventricular pacemaker cells
Arterioles		
Coronary	α_1, α_2, V_1; β_2, D_1, V_2 (via NO)	Constriction; dilation
Skin and mucosa	α_1, α_2, V_1	Constriction
Skeletal muscle	α_1, V_1; β_2	Constriction; dilation
Cerebral	α_1, V_1; V_2 (via NO)	Constriction (slight); dilation
Pulmonary	α_1; β_2, V_2 (via NO)	Constriction; dilation
Abdominal viscera (mesentery)	α_1, V_1; β_2, D_1	Constriction; dilation
Renal	α_1, α_2, V_1; β_1, β_2, D_1	Constriction; dilation
Veins (systemic)	α_1, α_2; β_2	Constriction; dilation
Lungs		
Tracheal/bronchial smooth muscle	β_2	Relaxation
Bronchial glands	α_1; β_2	Decreased; increased secretion
Stomach		
Motility and tone	α_1, α_2, β_1, β_2	Decreased (usually)
Sphincter	α_1	Contraction (usually)
Secretions	α_2	Inhibition
Intestine		
Motility and tone	α_1, α_2, β_1, β_2; V_1	Decreased (usually); increased?
Sphincters	α_1	Contraction
Secretions	α_2	Inhibition
Kidney		
Renin secretion	α_1; β_1	Decreased; increased
Reabsorption of water	V_2	Increased
Skeletal muscle	β_2	Increased contractility, glyconeogenesis, K^+ uptake
Liver	α_1, β_2	Glycogenolysis and gluconeogenesis
Fat cells	α_1, β_1, β_2	Lipolysis (thermogenesis)

Based on data from references 6–19, 49–53.

vascular and bronchiolar smooth muscle tone and myocardial contractility. These effects are mediated by sympathetic adrenergic receptors of the autonomic nervous system located in the vasculature, myocardium, and bronchioles. Postsynaptic adrenoceptors are located at or near the synaptic junction. These receptors can be activated by naturally circulating or exogenous catecholamines (e.g., norepinephrine, epinephrine, and phenylephrine), whereas presynaptic adrenoceptors are stimulated by locally released neurotransmitters (e.g., norepinephrine) and are controlled by a negative feedback mechanism.

The signal transduction pathways associated with catecholamine and vasopressin-induced effects in the heart and blood vessels are illustrated in Figure 30–1. [6–19,49–53] Agonists of β-adrenoceptors and dopamine (D_1) receptors stimulate adenylate cyclase by a G-protein (G_s)–dependent mechanism (Fig. 30–1, top). Adenylate cyclase generates cyclic adenosine monophosphate (cAMP) from adenosine triphosphate (ATP). cAMP-dependent protein kinase A, which is activated by elevations in intracellular cAMP, phosphorylates target proteins to modify cellular function. Through these mechanisms, β_1-adrenoceptor activation exerts positive inotropic and chronotropic effects in the heart, and β_2-adrenoceptor and D_1-receptor activation induces vascular smooth muscle relaxation. Agonists of α_1-adrenoceptors stimulate phospholipase C-β (PLC-β) through a G-protein (G_q)–dependent process (Fig. 30–1, bottom). PLC-β produces inositol trisphosphate and diacylglycerol from cell membrane phosphatidylinositol bisphosphate. Diacylglycerol activates protein kinase C, an enzyme that phosphorylates several key proteins (e.g., extracellular signal-regulated kinases, c-Jun NH2-terminal kinases, and mitogen-activated protein kinases) that modify cellular function (e.g., hypertrophy). Inositol trisphosphate elicits the release of calcium from intracellular stores, such as the sarcoplasmic reticulum. Calcium forms a complex with calmodulin, which then activates calcium–calmodulin-dependent protein kinases (CaMK). CaMKs phosphorylate target proteins to alter cellular function. Myosin light-chain kinase is an example of a CaMK. Its action of phosphorylating myosin light chain leads to vascular smooth muscle contraction.

The normal heart contains primarily postsynaptic β_1-receptors, which when stimulated cause increased rate and force of contraction. This effect is mediated by activation of adenylate cyclase and subsequent generation and accumulation of cAMP. Stimulation of postsynaptic cardiac α_1-receptors causes a significant increase in contractility without an increase in rate, an effect mediated by PLC rather than adenylate cyclase. The increased contractility is more pronounced at lower heart rates and has a slower onset and longer duration in comparison with β_1-mediated inotropic response. Presynaptic α_2-adrenoceptors also are found in the heart and appear to be activated by norepinephrine released by the sympathetic nerve itself. Their activation inhibits further norepinephrine release from the nerve terminal.

Both presynaptic and postsynaptic adrenoceptors are present in the vasculature. Postsynaptic α_1- and α_2-receptors mediate vasoconstriction, whereas postsynaptic β_2-receptors induce vasodilation. Presynaptic α_2-receptors inhibit norepinephrine release in the vasculature, also promoting vasodilation. Presynaptic β_1-adrenoceptors promote neurotransmitter release. Stimulation of peripheral D_1-receptors produces renal, coronary, and mesenteric vasodilation and a natriuretic response. Stimulation of D_2-receptors inhibits norepinephrine release from sympathetic nerve endings, sequesters prolactin and aldosterone, and may induce nausea and vomiting. D_1- and D_2-receptor stimulation also suppresses peristalsis and may precipitate ileus.

5 Vasopressin-induced vasoconstriction occurs through a variety of direct and indirect mechanisms.[51–53] Stimulation of vascular vasopressin $(V)_1$ receptors causes vasoconstriction by receptor-coupled activation of PLC and calcium release from intracellular stores via secondary messengers similar to α_1-adrenergic stimulation (Fig. 30–1, bottom). Vasopressin also directly inhibits vascular potassium-sensitive ATP channels to produce vasoconstriction (Fig. 30–1, bottom). V_1-receptor stimulation inhibits the actions of IL-1β and thereby facilitates vasoconstriction. Vasopressin also increases the activity of adrenergic receptors. The greatest vasoconstriction occurs in the skin and soft tissue, skeletal muscle, fat tissue, pancreas, and thyroid gland. In contrast, vasopressin causes vasodilation in the cerebral, pulmonary, coronary, and selected renal vascular beds by enhancing endothelial NO release through V_1-receptor stimulation in these tissues.[51–53] Vasopressin has minimal to no inotropic or chronotropic effects.

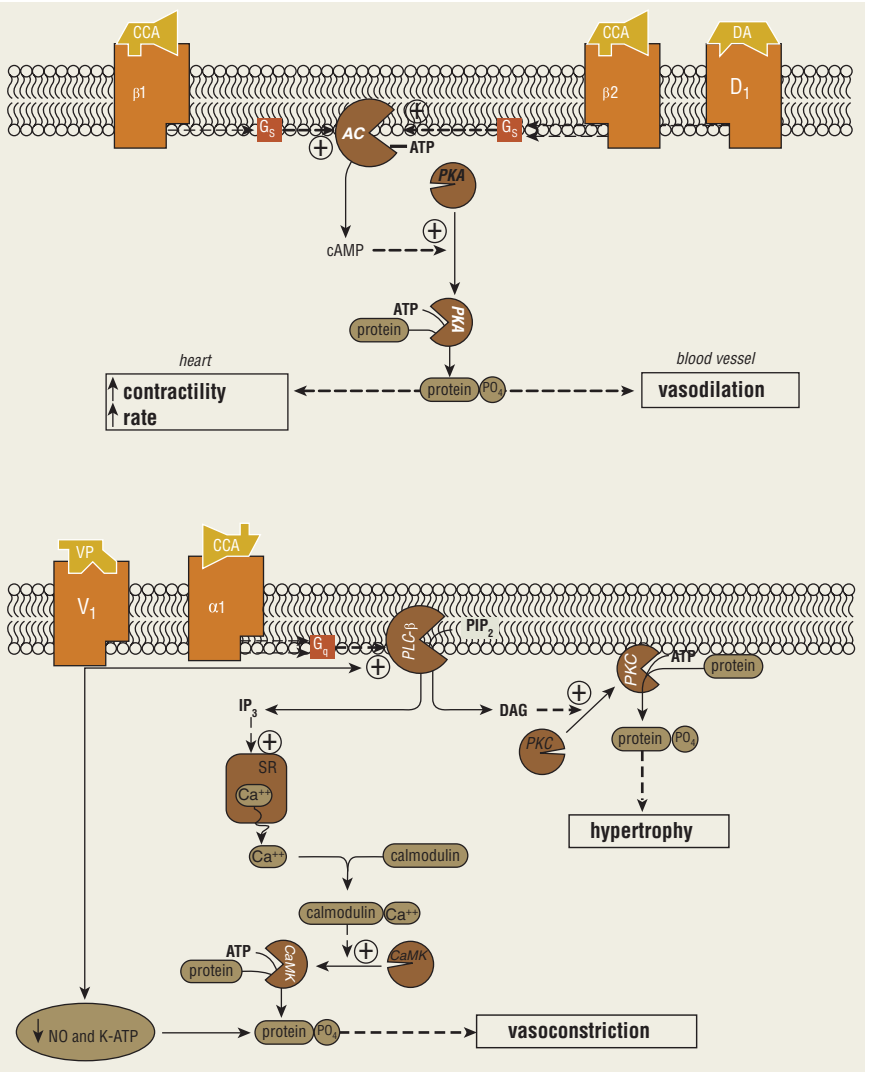

FIGURE 30-1. Signal transduction pathways in heart and blood vessels. Top: Catecholamine (CCA)-induced effects mediated in heart (β_1) or vascular smooth muscle (β_2, D_1). (AC, adenylate cyclase; ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate; PKA, cAMP-dependent protein kinase; +, stimulation.) Bottom: CCA (α_1) and vasopressin (VP)-induced actions in vascular smooth muscle. (Ca++, calcium ion; CaMK, calcium/calmodulin-dependent protein kinase; DAG, diacylglycerol; IP3, inositol trisphosphate; NO, nitric oxide; PIP2, phosphatidylinositol bisphosphate; PKC, protein kinase C; PLC-β, phospholipase C-β; SR, sarcoplasmic reticulum.) These pathways have been extensively simplified, and denoted cellular effects represent one of many produced. *(Figure based on data from references 6–19, 49–53.)*

V_2 receptors located in the kidneys are responsible for the antidiuretic properties of vasopressin.[51–53] Stimulation of V_2 receptors facilitates integration of aquaporins into the luminal cell membrane of distal tubules and collecting duct capillaries to increase permeability and thus retain intravascular volume. However, vasopressin stimulation of V_1 receptors causes vasoconstriction of efferent arterioles and relative vasodilation of afferent arterioles to increase glomerular perfusion pressure and filtration rate to enhance urine production.

Vasopressin rapidly increases serum cortisol concentration by stimulating V_3 receptors in the pituitary gland to enhance the release of adrenocorticotropic hormone (ACTH).[51–53] Cortisol helps regulate the proinflammatory state associated with sepsis and increases blood pressure through several mechanisms, including inhibition of inducible NOS (iNOS) to reduce NO production, reversal of adrenergic receptor desensitization, and increased intravascular volume through retention of sodium and water.

ALTERED ADRENOCEPTOR FUNCTION: IMPLICATIONS FOR CRITICALLY ILL PATIENTS

4 Most of the work describing receptor function and associated clinical pharmacology has been performed in either animal models or human volunteers. In critically ill septic patients, derangements in adrenergic receptor activity may result in resistance to exogenously administered catecholamine.[6–19,49,50] This "desensitization" frequently is characterized by myocardial and vascular hyporesponsiveness to high dosages of inotropes and vasopressor agents. Prolonged exposure of vascular endothelial tissue to vasopressor drugs (α-adrenergic agonists) or endogenous catecholamines may promote additional receptor downregulation. Increased endogenous catecholamine concentrations have been reported in endotoxemic and other critically ill patients, suggesting an acquired adrenergic receptor defect and desensitization of adrenergic receptors and alteration in voltage-sensitive calcium channels. The problem in critically ill patients may be related to decreased receptor activity or density. However, in patients with septic shock, catecholamine concentrations are even higher, so abnormalities in adrenergic receptor function are greater, with associated reductions in the concentrations of intracellular signal transduction mediators. The worsened receptor abnormality may be explained by defects distal to the receptor site, such as uncoupling of adrenergic receptors from adenylate cyclase or PLC, or dysfunction in the regulatory G-protein unit of signal transduction pathways.

In addition to catecholamines, circulating inflammatory cytokines may be partly responsible for distal alterations.[34] Macrophage-derived IL-1 and TNF-α produce impaired coupling of β-adrenoceptors to adenylate cyclase. Patients with septic shock exhibit impaired β-adrenergic receptor stimulation of cAMP associated with myocardial hyporesponsiveness to various vasopressors and inotropes. However, increased chronotropic sensitivity to β-adrenergic stimulation with hypersensitivity of the adenylate cyclase system to isoproterenol stimulation also has been reported in animal models of bacteremia and endotoxemia. In the

presence of intrinsic myocardial dysfunction and increased metabolic demands, this dysfunctional adrenergic system is incapable of mobilizing functional cardiac reserve to maintain adequate myocardial performance.[45,46]

IL-1 and TNF-α suppress gene expression of α_1-adrenoceptors, resulting in fewer receptor proteins. Overproduction of NO by iNOS directly contributes to vasodilation by cyclic guanosine monophosphate–mediated smooth muscle relaxation. NO indirectly produces vasodilation by combining with superoxide to form peroxynitrite, a highly toxic reactive species that causes endothelial dysfunction, uncoupling of α_1-adrenoceptors to PLC, and deactivation of catecholamines. The result of sepsis-induced inflammation is a system that promotes adrenergic receptor dysfunction to accentuate vasodilation and shock.[6–19,49,50]

5 Functional α_1-adrenergic receptor changes occur at various stages of sepsis; thus, adrenoceptor sensitivity may be time dependent during progression of sepsis to septic shock. The findings are not always consistent in various animal models of sepsis and in critically ill septic patients. Time-dependent alterations in the production of NO, a potent vasodilator, may explain the apparent differences in vascular reactivity to phenylephrine during the phases of endotoxemia. This finding suggests that the clinical response to vasopressors and possibly inotropic agents is variable during the stages of hemodynamic, myocardial, and peripheral vascular derangements of septic shock. β-adrenergic receptor changes are present within 24 to 48 hours of septic shock. In summary, α- and β-adrenergic receptor derangements may vary among patients and during each bacteremic insult; therefore, doses of catecholamines vary among patients and during the insult.[6–19,49,50] For these reasons, these drugs should be dosed to clinical end points and not to arbitrary maximal doses. High dosages are frequently required.

RELATIVE DEFICIENCIES OF VASOPRESSIN AND CORTISOL

14 Endogenous arginine vasopressin, a peptide hormone also known as antidiuretic hormone, is important for osmoregulation under normal physiologic conditions. Vasopressin is produced in the hypothalamus, stored in the posterior pituitary, and released from magnocellular neurons of the hypothalamus.[51–53] Increased serum osmolality and hypovolemia are the major stimuli for vasopressin release.[51–53] Other stimuli commonly associated with shock are dopamine, histamine, angiotensin II, prostaglandins, pain, hypoxia, acidosis, hypotension, hypercarbia, and α_1-adrenergic receptor stimulation. Vasopressin release is inhibited by NO, natriuretic peptides, γ-aminobutyric acid, β-adrenergic receptor stimulation, and α_2-adrenergic receptor stimulation.[51–53]

Normal serum vasopressin concentrations are <4 pg/mL.[51–53] Serum vasopressin concentrations are elevated with hypotension. Vasopressin response in septic shock is biphasic. During the first 8 hours of septic shock requiring catecholamine adrenergic therapy, serum concentrations of vasopressin are appropriately high to help maintain blood pressure and organ perfusion. Thereafter, serum vasopressin concentrations decline dramatically over the next 96 hours to physiologically normal but inappropriately low values, resulting in a state of "relative deficiency." In contrast, serum vasopressin concentrations remain elevated in patients with cardiogenic shock. Administration of vasopressin at 0.01 to 0.06 units/min produces concentrations similar to those observed in early septic shock and other hypotensive states; however, vasopressin concentrations do not correlate with blood pressure.[51–53] Administration of vasopressin improves arterial pressure while minimizing the dose of catecholamine vasopressors.[51–53]

The mechanism of vasopressin insufficiency in septic shock is not well understood. Neurohypophyseal stores in the posterior lobe of the pituitary gland are depleted during septic shock, likely as a result of excessive and continuous baroreceptor stimulation that eventually exhausts the limited vasopressin secretory stores. In addition, secretion of vasopressin is inhibited by enhanced endothelial production of NO, high circulating concentrations of adrenergic agonists (both endogenous and exogenous), and tonic inhibition by stretch receptors in response to volume replacement and mechanical ventilation.[51–53]

14 As with vasopressin, during sepsis a state of "relative adrenal insufficiency" is produced by continuous activation of the hypothalamic–pituitary–adrenal axis by IL-1, IL-6, and TNF-α that causes depletion of cortisol in the adrenal glands.[54] Administration of corticosteroids improves arterial pressure while minimizing the dose of catecholamine vasopressors.[55,56] Current proposed mechanisms of the vasoconstrictor effect of corticosteroids include increasing the number and stimulating the function of α_1- and β-adrenergic receptors and attenuating the production of inflammatory mediators responsible for vasodilation.

The use of corticosteroids for treatment of septic shock has been a topic of controversy for many years. Meta-analyses of early studies of steroids in patients with sepsis demonstrated a lack of benefit and potential harm in sepsis and septic shock.[57,58] Interest in corticosteroid use is renewed because of the increased awareness of adrenocortical insufficiency in critically ill patients with septic shock.[54] Relative adrenal insufficiency has been defined as a random cortisol concentration <10 mcg/dL (278 nmol/L) or an increase of <9 mcg/dL (250 nmol/L) to a dose of synthetic ACTH irrespective of the initial serum cortisol level.[59] Although absolute insufficiency is rare, relative adrenocortical insufficiency is present in 50% to 70% of patients with septic shock and is associated with a poor outcome.[54–62]

An elevated random cortisol concentration (>34 mcg/dL) is an independent predictor of mortality.[59] Mortality is further increased if ACTH response is <9 mcg/dL, suggesting that the risk of mortality is greatest in situations of adrenal gland "fatigue" (i.e., degree of stress is not matched by sufficient cortisol production by the adrenal glands despite operating at maximal functional capacity).

CLINICAL PHARMACOLOGY OF VASOPRESSORS AND INOTROPES

5 14 The receptor selectivity of clinically used, catecholamine-based vasopressors and inotropes and hemodynamic effects are listed in Table 30–4.[6–19,49–53] In general, these drugs are fast acting, with short durations of action. As such, these drugs are given as continuous infusions and titrated rapidly to predetermined effects.[7] Vasopressin is administered as a replacement dosage of 0.01 to 0.04 units/min and should not be titrated.[51–53] Careful monitoring and calculation of infusion rates are advised for all vasopressors because dosing adjustments are made frequently, and varying admixtures and concentrations are used in volume-restricted patients.

9 Dopamine has been described as having dose-related receptor activity at D_1-, D_2-, β_1-, and α_1-receptors (Table 30–4).[6–19,49,50] Unfortunately, this dose–response relationship has not been confirmed in critically ill patients. In patients with septic shock, great overlap of hemodynamic effects occurs, even at dosages as low as 3 mcg/kg/min.[63] Tachydysrhythmias are common due to the release of endogenous norepinephrine by dopamine entering the sympathetic nerve terminal. Dopamine may increase PAOP through pulmonary vasoconstriction. This drug also may depress ventilation and worsen hypoxemia in patients dependent on the hypoxic ventilatory drive. However, it is a first-line option for the initial therapy in patients with septic shock because it increases blood pressure by increasing myocardial contractility and vasoconstriction.[7]

9 Norepinephrine is a combined α- and β-agonist that produces vasoconstriction primarily via its more prominent α-effects on all

TABLE 30-4 Receptor Pharmacology and Adverse Events of Selected Inotropic and Vasopressor Agents Used in Septic Shock[a]

Agent (Adverse Events)	α_1	α_2	β_1	β_2	D	V_1	V_2
Dobutamine (0.5–4 mg/mL D_5W or NS)	Tachycardia, dysrhythmias, hypotension						
2–10 mcg/kg/min	+	0	++++	++	0	0	0
>10–20 mcg/kg/min	++	0	++++	+++	0	0	0
Dopamine (0.8–3.2 mg/mL D_5W or NS)	Tachycardia, dysrhythmias, decreased Pao_2, mesenteric hypoperfusion, gastrointestinal motility inhibition, T-cell inhibition						
1–3 mcg/kg/min	0	0	+	0	++++	0	0
3–10 mcg/kg/min	0/+	0	++++	+	++++	0	0
>10–20 mcg/kg/min	+++	0	++++	+	0	0	0
Epinephrine (0.008–0.016 mg/mL D_5W or NS)	Tachycardia, dysrhythmias, decreased Pao_2, mesenteric hypoperfusion, increased lactate, hyperglycemia, immunomodulation						
0.01–0.05 mcg/kg/min	++	++	++++	+++	0	0	0
0.05–3 mcg/kg/min	++++	++++	+++	+	0	0	0
Norepinephrine (0.016–0.064 mg/mL D_5W)	Mixed effects on myocardial performance and mesenteric perfusion, peripheral ischemia						
0.02–3 mcg/kg/min	+++	+++	+++	+/++	0	0	0
Phenylephrine (0.1–0.4 mg/mL D_5W or NS)	Mixed effects on myocardial performance, peripheral ischemia						
0.5–9 mcg/kg/min	+++	+	+	0	0	0	0
Vasopressin (0.8 units/mL D_5W or NS)	Mixed effects on myocardial performance, mesenteric hypoperfusion, peripheral ischemia, hyponatremia, thrombocytopenia						
0.01–0.04 units/min	0	0	0	0	0	+++	+++

[a]Activity ranges from no activity (0) to maximal (++++) activity.
D, dopamine; D_5W, dextrose 5% in water; NS, normal saline; Pao_2, arterial oxygen pressure; V, vasopressin.
Based on data from references 6–19, 49–53.

vascular beds, thus increasing SVR.[6–19,49,50] Norepinephrine administration generally produces either no change or some increase in CO. In addition to dopamine, norepinephrine is considered an option for initial vasopressor therapy for septic shock.[7,63]

⑩ Phenylephrine is a pure α_1-agonist and increases blood pressure through vasoconstriction.[6–19,49,50] Given the presence of cardiac α_1-receptors, phenylephrine also may increase contractility and CO. It is a therapeutic option in hypotensive patients experiencing a tachyarrhythmia when a vasopressor with minimal to no β_1-agonist activity is indicated.[7]

⑪ Epinephrine exerts combined α- and β-agonist effects.[6–19,49,50] At the high epinephrine infusion rates used for patients with septic shock, predominantly α-adrenergic effects are observed, and SVR and MAP are increased. While epinephrine traditionally has been reserved as the vasopressor of last resort due to peripheral vasoconstriction, particularly in the splanchnic and renal beds, it is considered second-line therapy according to the current guidelines.[7] It is widely used in other countries where other agents may not be readily available or are relatively expensive.

⑫ Dobutamine, a synthetic catecholamine, is primarily a selective β_1-agonist with mild β_2- and vascular α_1-activity, resulting in strong positive inotropic activity without concomitant vasoconstriction.[6–19,49,50] In comparison with dopamine, dobutamine produces a larger increase in CO and is less arrhythmogenic. α_1-Adrenoceptors in the heart are directly stimulated by the (–) isomer of dobutamine, but β_1 and β_2 activity resides in the (+) isomer. The strong inotropic action of dobutamine is a function of its structure, the additive effect of cardiac α_1- and β_1-agonist activity, and a relatively weak chronotropic effect limited to the (+) isomer action on the β-receptors. Clinically, β_2-induced vasodilation and the increased myocardial contractility with subsequent reflex reduction in sympathetic tone lead to a decrease in SVR. Dobutamine is used optimally for patients in low CO states with high filling pressures (e.g., CI <3 L/min/m^2, left ventricular dysfunction demonstrated with echogardiography, or $Scvo_2$ <70%) or in those in cardiogenic shock; however, vasopressors may be needed to counteract arterial vasodilation.[7,30]

⑭ Unlike adrenergic receptor agonists, the vasoconstrictive effects of vasopressin are preserved during hypoxia and severe acidosis. Initiating vasopressin at ≤0.04 units/min in patients with septic shock increases SVR and arterial blood pressure to reduce the dose requirements of catecholamine adrenergic agents.[51–53,64] These effects are rapid and sustained. Organ-specific vasodilation reduces pulmonary artery pressure and may preserve cardiac and renal function. It may enhance urine production, likely due to increased glomerular filtration rate.[51–53] At dosages exceeding 0.04 units/min, however, vasopressin is associated with ischemia of the mesenteric mucosa, skin, and myocardium. Limiting the dosage to a maximum of 0.04 units/min may minimize the development of these adverse effects. At present, vasopressin is not recommended as a replacement for norepinephrine or dopamine in patients with septic shock but may be considered as adjunctive therapy in patients who are refractory to catecholamine vasopressors despite adequate fluid resuscitation.[7] If used, vasopressin should be administered at dosages not exceeding 0.04 units/min.[7,51–53,64]

CLINICAL APPLICATION

Resuscitation of Septic Shock

⑥ ⑦ ⑨ Initial hemodynamic therapy for septic shock is the administration of intravenous fluid (20–40 mL/kg of crystalloid fluid), with the goal of attaining CVP of 8 to 12 mm Hg or 15 mm Hg in mechanically ventilated patients or patients with abdominal distension or preexisting ventricular dysfunction.[6–19,30] Crystalloid fluids (e.g., normal saline, Ringer lactate) and colloid fluids (e.g., albumin, hydroxyethyl starch, blood products) are considered equivalent for shock resuscitation.[65] Crystalloid fluids are generally preferred unless patients are at risk for adverse events from redistribution of intravenous fluids to extravascular tissues and/or are fluid restricted (e.g., patients with renal dysfunction, decompensated heart failure, ascites compromising diaphragmatic function).[7] Recent data suggest hydroxyethyl starch may increase the risk of acute renal dysfunction in a dose-dependent manner and possibly enhance mortality.[66] Its use warrants caution.

⑧ Traditional vasopressors and inotropes used for hemodynamic support of patients with hypotension refractory to fluid administration include dopamine, norepinephrine, phenylephrine epinephrine, and dobutamine. Optimizing MAP to 65 mm Hg as the goal of vasopressor therapy does not uniformly correlate with decreased

mortality in patients with septic shock but global perfusion may be improved.[17–21] Historically, significant concerns about the adverse effects of vasopressors limited their use. The past focus of achieving supranormal oxygen-transport variables also yielded poor results in patients with septic shock.[33] In fact, normalization of systemic Do_2 and Vo_2, whether spontaneously or with intervention, is associated with improved outcome and is not dependent on administration of vasopressor agents.[33] Part of the inability to detect an improvement with vasopressor or inotropic therapies may result from the limited ability to quantify regional tissue perfusion. However, use of early goal-directed therapy to MAP ≥65 mm Hg and $Scvo_2$ ≥70% reduces mortality in patients with sepsis and septic shock.[30]

6 7 8 9 Dosage titration and monitoring of vasopressor and inotropic therapy should be guided by the "best clinical response" and the goals of early goal-directed therapy.[6–19,30] Dopamine or norepinephrine is considered the agent of choice as initial vasopressor therapy.[7] Norepinephrine may be added in cases where suboptimal response is obtained from dopamine but adding dopamine to norepinephrine does not provide a hemodynamic benefit.[7] Phenylephrine may be tried as the initial vasopressor in cases of severe tachydysrhythmias.[7] The results of a recent survey of critical care pharmacists showed norepinephrine is the preferred initial agent (57%), followed by dopamine (28.6%) and phenylephrine (9.3%).[67] Norepinephrine is the most common second-line agent when used to augment dopamine or phenylephrine, whereas vasopressin is most frequently added to norepinephrine. Regardless of which vasopressor is chosen, low dosage rates are initiated and titrated rapidly (usually every 5–15 minutes) to clinical response. Clinically effective dosing of vasopressors and inotropes in septic shock often requires doses much larger than recommended by most references.[6–19] These large infusion rates must be tempered with the development of adverse effects. The goal is to use the minimally effective infusion rate while minimizing evidence of myocardial ischemia (e.g., tachydysrhythmias, electrocardiographic changes), renal (decreased glomerular filtration rate and/or urine output), splanchnic/gastric (low pHi, bowel ischemia), or peripheral (cold extremities) hypoperfusion, and worsening PaO_2, PAOP, and other hemodynamic variables.

13 Therapy with catecholamine vasopressors and inotropes is continued until myocardial depression and vascular hyporesponsiveness (i.e., blood pressure) of septic shock improve, usually measured in hours to days.[7] Discontinuation of vasopressor or inotropic therapy should be executed slowly; therapy should be "weaned" to avoid a precipitous worsening in regional and systemic hemodynamics. Careful monitoring of global and regional end points also should be geared toward discontinuation of vasopressors and inotropes as soon as the patient is hemodynamically stable. This requires constant observation. Because vasopressors and inotropes often are started while the patient is not yet optimally volume resuscitated, clinicians should reevaluate intravascular volume status continuously so that the patient can be weaned from the vasopressor as soon as possible. Dosage rates should be titrated carefully downward approximately every 10 minutes to determine if the patient can tolerate gradual withdrawal and eventual discontinuation of the vasopressor and/or inotrope. Discontinuation of agents may occur only minutes to hours after their initiation, or it may take days to weeks. Septic shock requiring vasopressor and/or inotropic support usually resolves within 1 week.

Comparative Studies of Catecholamine Vasopressors

7 9 In a randomized study of 32 septic shock patients unresponsive to volume resuscitation, norepinephrine alone was superior to dopamine in achieving and maintaining preset hemodynamic (MAP of at least 80 mm Hg) and oxygen-transport variables for at least 6 hours (93% vs 31% of patients; P <0.001).[68] Of the 11 patients who did not respond to dopamine, 10 achieved the desired hemodynamic goal when norepinephrine was added. The authors suggested that differences between the two agents resulted from norepinephrine's combined increase in Vo_2 and decrease in lactate concentrations due to reversal of splanchnic ischemia and efficient hepatic clearance of lactate or a preferential increase in Do_2 to areas of greatest oxygen demand, thus optimizing O_2ER. The same investigators showed in a prospective, observational cohort study of 97 adult patients with septic shock that use of norepinephrine to provide hemodynamic support was associated with a significant decrease in mortality (day 7: 28% vs 40%; P <0.005; day 28: 55% vs 82%; P <0.001; at hospital discharge: 62% vs 84%; P <0.001).[69] Using stepwise logistic regression analysis, norepinephrine was found to be the only factor associated with significantly improved survival (P = 0.03). Despite the drawback of the lack of randomization, this study is the first to demonstrate a survival benefit with any vasopressor. The results of another observational study found dopamine was an independent factor associated with ICU mortality in all 1,058 patients with shock (OR, 1.67; 95% CI, 1.19–2.35; P = 0.003) and the subgroup of 462 patients with septic shock (OR, 2.05; 95% CI, 1.25–3.37; P = 0.005).[70] Yet another observational study of 277 patients with septic shock found dopamine to be associated with 28-day mortality (OR, 6.2; 95% CI, 1.5–25; P = 0.01).[71] In contrast, a fourth observational study of 458 patients with community-acquired sepsis found norepinephrine was independently associated with 28-day mortality (OR, 2.5; 95% CI, 1.41–4.43; P = 0.002), whereas dopamine had no effect.[72] The results of a recent randomized study of norepinephrine and dopamine in 1,679 patients with shock unresponsive to volume resuscitation found similar 28-day mortality rates (48.5% vs 52.5% of patients; P = 0.10) although death from refractory shock tended to occur less frequently with norepinephrine (41% vs 46%; P = 0.05).[73] Mortality rate was significantly lower in the subgroup of 280 patients with cardiogenic shock that received norepinephrine (P = 0.03). Overall, patients receiving norepinephrine had fewer arrhythmic events (12.4% vs 24.2%; P <0.001) despite using dobutamine more frequently, had more vasopressor-free days, and were less likely to require open-label vasopressor support (20% vs 26%; P <0.001). Limitations of this landmark study include combining heterogeneous shock etiologies (cardiogenic, septic, hypovolemic, and other), the use of a relatively conservative definition of "shock unresponsive to fluid administration" (only 1 L of crystalloid or 0.5 L of colloid), the use of open-label norepinephrine in patients with inadequate hemodynamic response to study drug regimens, and the lack of standardization of other shock therapies that affect hemodynamic variables (e.g., corticosteroids, vasopressin, dobutamine, additional fluid administration). Another recent study randomized 252 septic shock patients found statistically similar 28-day mortality rates between norepinephrine and dopamine (43% vs 50%; P = 0.282).[74] Similar to the aforementioned study, arrhythmic events were less likely to occur with norepinephrine (5.3% vs 23.3%; P <0.0001).

7 9 11 Two randomized, double blind studies compared epinephrine with norepinephrine in 330 and 280 patients with septic shock, respectively.[75,76] Both studies found similar 28-day mortality rates with epinephrine and norepinephrine (40% vs 31%; P = 0.31; and 22.5% vs 26.1%; P = 0.48). Time to hemodynamic recovery and vasopressor withdrawal were also similar between agents in both studies. One study found more events of tachydysrhythmias with epinephrine leading to study discontinuation.[75] Both studies also showed that epinephrine was associated with lower arterial pH values and higher serum lactate concentrations over the first days of therapy, possibly demonstrating

deleterious circulation, exaggerated glycolysis, or mobilization of lactate with epinephrine.

Low ("Renal") Dose Dopamine

7 9 Historically, acute kidney injury from sepsis was believed to be due to renal ischemia.[77] In the critical care setting, low dosages (1–3 mcg/kg/min) of dopamine once were advocated for use in patients with septic shock receiving vasopressors with or without oliguria.[78] The goal of this therapy is to minimize or reverse renal vasoconstriction caused by other pressors, to prevent oliguric renal failure, or to convert oliguric to nonoliguric renal failure. At low dosages, dopamine has been shown to increase urine production as a result of enhanced renal blood flow from its D_1-receptor–mediated vasodilation, its D_2-receptor–mediated natriuretic effects (inhibition of Na^+/K^+ ATP of renal tubular cells), or its β_1-receptor–mediated increase in cardiac index.[49,50] In healthy subjects, the addition of dopamine to incremental doses of norepinephrine may blunt norepinephrine-induced renal vasoconstriction, thereby maintaining renal blood flow, natriuresis, urine production, and glomerular filtration. These effects also have been observed during the course of dopamine administration in oliguric and nonoliguric patients with septic shock. For this reason, low doses of dopamine sometimes are added to other vasopressors (e.g., norepinephrine). Tolerance to the vasodilatory effects of dopamine after 24 to 48 hours is evident in nonoliguric patients with sepsis syndrome.

Two studies have settled the debate surrounding low-dose dopamine. Friedrich et al. performed a meta-analysis to determine if low-dose dopamine reduces mortality or the need for dialysis in patients with critical illness.[78] Among 61 clinical trials (N = 3,359), low-dose dopamine had no effect on mortality (RR, 0.96; 95% CI, 0.78–1.19), need for dialysis (RR, 0.93; 95% CI, 0.76–1.15), or occurrence of adverse events (RR, 1.13; 95% CI, 0.90–1.41). Low-dose dopamine improved urine production by 24% (95% CI, 14%–35%) on the first day of therapy but failed to maintain this effect on days 2 and 3. No improvements in serum creatinine concentration (4% relative increase; 95% CI, 1%–7%) and measured creatinine clearance (6% relative increase; 95% CI, 1%–11%) occurred within 24 hours of initiating dopamine. One adequately designed prospective, controlled trial has been conducted with low-dose dopamine in critically ill patients.[79] Bellomo et al. randomized 328 critically ill patients with early renal dysfunction to either low-dose dopamine (2 mcg/kg/min) or placebo and found no differences in peak serum creatinine concentration (2.77 ± 1.63 mg/dL vs 2.82 ± 1.66 mg/dL), increase in serum creatinine concentration (0.7 ± 1.21 mg/dL vs 0.75 ± 1.22 mg/dL), need for renal replacement therapies (27.7% vs 24.5%), and urine production at any time point.[79] On the basis of available evidence, low-dose dopamine for treatment or prevention of acute renal failure cannot be justified and should be eliminated from routine clinical use in the ICU.[7]

Evidence now suggests that the etiology of acute renal failure from sepsis is due to efferent arteriole vasodilation.[76] Enhanced urine production has been shown to occur in hyperdynamic shock with use of agents that constrict the efferent arteriole such as vasopressin and norepinephrine.[49,50] In the randomized study of norepinephrine and dopamine by Martin et al.,[68] urine production increased with norepinephrine but not with dopamine (22 ± 7 mL/h to 189 ± 52 mL/h vs 24 ± 6 mL/h to 8.2 ± 10 mL/h; P <0.001). Adding norepinephrine to the dopamine group increased urine production to 107 ± 125 mL/h. An increase in urine production may be due to the localized vasoconstrictive effect of norepinephrine in the kidney (greater vasoconstriction of the efferent arteriole than the afferent arteriole) or enhanced glomerular filtration rate from increased renal perfusion pressure secondary to elevated CO and SVR. Delineating these differential effects of improved arterial blood pressure and CO from regional renal effects is difficult.

Vasopressin

14 Small studies of septic shock patients demonstrate that initial therapy with vasopressin achieves blood pressure control as effectively as traditional catecholamine vasopressors but the response is delayed.[51–53] Therefore, vasopressin therapy should not be initiated as first-line therapy. Several small studies showed that adjunctive vasopressin therapy reduces the dose requirements of catecholamine vasopressors and maintains blood pressure to expedite the discontinuation of catecholamine vasopressors.[51–53] Some studies document enhancement of urine production.[51–53] The results of a randomized, double-blind study of 776 patients with septic shock requiring catecholamine vasopressors showed that 28-day mortality rates were similar when vasopressin 0.01 to 0.03 units/min or norepinephrine 5 to 15 mcg/min was added to traditional catecholamine therapy (35.4% vs 39.3%; P = 0.26).[64] A trend toward reduced 28-day mortality favored vasopressin in the subset of patients categorized as having less severe septic shock defined by a baseline norepinephrine requirement of <15 mcg/min (26.5% vs 35.7%; P = 0.05). This trend was evident when sepsis severity was defined by lactate quartiles or number of organ failures, suggesting that adjunctive vasopressin may be most beneficial when it is started prior to escalation of therapy with catecholamine vasopressors. Posthoc analyses demonstrated greatest benefit with early vasopressin treatment relative to the onset of shock. The adverse event profiles were similar between groups. Of note, vasopressin therapy expedited the discontinuation of catecholamine vasopressors in all patients and helped preserve renal function in patients with acutely declining urine production.[64] Whereas V_2 stimulation promotes water retention from the distal tubules and collecting ducts, V_1 receptors cause vasoconstriction of efferent arterioles and relative vasodilation of afferent arterioles to increase glomerular perfusion pressure and filtration rate, enhancing urine production. In the studies reporting benefit on renal function, the maximum dosage used was 0.08 units/min.[51–53,64] Use of vasopressin for preventing dose escalation of adrenergic agents should be considered, but the risks must be considered prior to initiating therapy. At present, vasopressin should not be used for the sole purpose of improving or maintaining renal function.[7]

CLINICAL CONTROVERSY: VASOPRESSIN

Adding vasopressin reduces the dose of traditional catecholamine therapies and may improve renal function. However, the occurrence of ischemic events to digits and splanchnic circulation may be increased with vasopressin. Therefore, the lowest possible dose should be implemented if vasopressin is used.

Corticosteroids

14 Since two meta-analyses reported in 1995,[57,58] several randomized controlled trials of low-dose corticosteroids in vasopressor-dependent septic shock patients have been published.[54–56,60,61] These studies use moderate physiologic dosages (200–300 mg/day) of hydrocortisone. A meta-analysis of five studies (N = 465) showed that steroid therapy was associated with an overall improvement in survival rate (RR, 1.23; 95% CI, 1.01–1.50; P = 0.036) and shock reversal (RR, 1.71; 95% CI, 1.29–2.26; P <0.001).[55] These effects were beneficial in both responders and nonresponders to ACTH stimulation testing. These studies also showed that low-dose corticosteroid administration improves hemodynamics and reduces the duration of vasopressor support. All of these studies differ from earlier studies in that steroids were administered at lower

total doses (hydrocortisone equivalents: 1,209 mg vs 23,975 mg; $P = 0.01$) starting later in septic shock (23 hours vs <2 hours; $P = 0.02$) for longer courses (6 days vs 1 day; $P = 0.01$) to patients with higher control group mortality rates (mean, 57% vs 34%; $P = 0.06$) who were more likely to be vasopressor dependent (100% vs 65%; $P = 0.03$). The relationship between corticosteroid dose and survival was linear, with survival benefit at low doses ($P = 0.02$). Another meta-analysis of 17 trials (N = 2,138) found similar results with long-term administration of corticosteroids associated with lower mortality in hospital (RR, 0.83; 95% CI, 0.68–1; $P = 0.05$) and at 28 days (RR, 0.84; 95% CI, 0.71–1; $P = 0.05$), reduced ICU stay by 4.49 days (95% CI, −7.04 to −1.95; $P < 0.001$), and greater shock reversal at 28 days (RR, 1.12; 95% CI, 1.02–1.23; $P = 0.02$).[56]

14 The results of these meta-analyses are heavily driven by data supplied by two, somewhat discordant, studies.[60,61] The first randomized 300 patients with septic shock within 8 hours of hypotension to placebo or a daily combination of hydrocortisone 50 mg IV every 6 hours and fludrocortisone 0.05 mg enterally for 7 days.[60] Similar to the meta-analyses, use of hydrocortisone reduced 28-day mortality (OR, 0.65; 95% CI, 0.39–1.07; $P = 0.09$), but all the benefit was seen in patients with adrenal insufficiency (OR, 0.54; 95% CI, 0.31–0.97; $P = 0.04$). The placebo group was more likely to continually require vasopressor therapy (hazard ratio [HR], 1.54; 95% CI, 1.10–12.16; $P = 0.01$), but differences between groups were exhibited only in patients with adrenal insufficiency (HR, 1.91; 95% CI, 1.29–2.84; $P = 0.001$). Approximately 77% of patients were deemed adrenally insufficient. The second study randomized 499 of 800 intended subjects with severe sepsis or shock within 72 hours of presentation to placebo or hydrocortisone 50 mg IV every 6 hours for 5 days followed by a 6-day taper.[61] Mortality rates were similar between groups (32% vs 34%), irrespective of adrenal function. Median time to shock reversal was shorter in patients receiving corticosteroid therapy (3.3 vs 5.8 days; $P < 0.001$), again irrespective of adrenal function. Unlike the previous study, however, only 47% of patients demonstrated adrenal insufficiency likely reflective of the entry criteria and lower overall mortality rate of the study population.

CLINICAL CONTROVERSY: CORTICOSTEROID THERAPY

Current guidelines do not suggest assessing adrenal function to determine the need for corticosteroid therapy.[7] Instead, they recommend initiating corticosteroids when hypotension is poorly responsive to vasopressor therapy. This is controversial given the limitations and differences between studies and the undefined term of "poorly responsive." Therefore, corticosteroid therapy may be considered in septic shock patients with adrenal insufficiency or when shock is refractory to other therapies.[54,62] Several questions surround the application of corticosteroid therapy in septic patients, including use in patients taking corticosteroids prior to ICU admission, most effective dosage regimen and duration, use of corticosteroids other than hydrocortisone, and the need for coadministration of fludrocortisone.

14 A post hoc analysis of the large vasopressin study revealed a significant interaction between vasopressin and corticosteroids.[80] In patients receiving vasopressin therapy, concurrent corticosteroid administration increased vasopressin concentrations by 33% to 67% over the initial 24 hours compared with patients only receiving vasopressin. The addition of corticosteroids to vasopressin was associated with reduced mortality compared with concurrent administration of corticosteroids and norepinephrine (35.9% vs 44.7%; $P = 0.03$). In the absence of corticosteroid therapy, however, mortality was greater with vasopressin therapy compared with norepinephrine (33.7% vs 21.3%; $P = 0.06$). Similar results were reported in a retrospective, matched assessment that found lower 7-day mortality was associated with combination therapy compared with vasopressin alone (19.1% vs 52.4%; $P = 0.02$).[81] This interaction warrants further investigation in studies.

Adverse Effects

5 7 9 10 11 Catecholamine vasopressors may result in adverse peripheral vasoconstrictive, metabolic, and dysrhythmogenic effects that limit or outweigh their positive effects on the central circulation.[6–19,49,50] Table 30–4 lists potential adverse effects of commonly used vasopressors and inotropes.[6–19,49–53] Norepinephrine, phenylephrine, and epinephrine can produce lactic acidosis secondary to excessive constriction in peripheral arterioles or enhanced glycogenolysis, or as a result of mobilization of lactate from peripheral tissues as a result of improved oxygenation. Additionally, excessive peripheral vasoconstriction may cause ischemia or necrosis of already poorly perfused tissues such as the skin and the mesenteric and splanchnic circulations. Some of these profound vasoconstrictive effects have been compounded by the concurrent use of other vasopressor agents in patients with septic shock who are significantly hypovolemic. These agents may be used in the context of late septic shock, where hypotension is refractory to less selective vasoconstrictors (e.g., dopamine) such that very large doses of norepinephrine or epinephrine or phenylephrine are required but provide little or no benefit. Myocardial ischemia and dysrhythmias may occur in patients with coronary artery disease, atherosclerosis, cardiomyopathies, left ventricular hypertrophy, congestive heart failure, or underlying dysrhythmias because of their inability to tolerate β_1 cardiac stimulation that mediates increases in CO. However, the effect usually is opposite in healthy myocardium and in young patients. β_1 Cardiac stimulation is well tolerated, ventricular filling pressures decrease, and CO and Do_2 increase, with a resulting increase in peripheral perfusion. The dysrhythmogenic potential of the catecholamine vasopressors includes a variety of resulting atrial and ventricular arrhythmias. Sympathomimetic vasopressors also have been found to possess immunomodulatory actions, primarily mediated by β_2-adrenergic actions (e.g., epinephrine) because almost all immune cells express this receptor.[34] The actions include downregulating expression of proinflammatory cytokines such as TNF-α by neutrophils, suppression of oxygen free radical production from neutrophils, and direct proapoptotic effects. Dopamine suppresses prolactin secretion from the anterior pituitary gland, which may lead to reduced T-cell responsiveness.[34] These effects may be either beneficial or deleterious by dampening harmful effects of oxygen free radical–mediated tissue injury or by reducing neutrophilic defense against bacteria.

Vasopressor catecholamines have the potential to cause extravasation-associated tissue damage if infusions infiltrate during peripheral administration. In the event of infiltration, an α-receptor antagonist such as phentolamine (10 mg in 10 mL saline) should be injected intradermally to reverse local vasoconstriction, with administration of vasopressor drugs into a large central vein.

Dopamine

7 8 9 13 Dopamine frequently is the initial vasopressor used for patients with septic shock.[6–19,67] Dosages of 5 to 10 mcg/kg/min are initiated to improve MAP. Most studies of patients with septic shock have shown that dopamine at these doses increases the cardiac index by improving contractility and heart rate, primarily from its β_1 effects. It increases MAP and SVR as a result of both increased CO and, at higher doses (>10 mcg/kg/min), its α_1 effects.

The clinical utility of dopamine as a vasopressor in the setting of septic shock is limited because large dosage rates frequently are necessary to maintain CO and MAP. At dosages exceeding 20 mcg/kg/min, further improvement in cardiac performance and regional hemodynamics is limited. Its clinical use frequently is hampered by tachycardia and tachydysrhythmias, which may lead to myocardial ischemia. Although tachydysrhythmias theoretically should not be expected to occur until administration of dopamine 5 to 10 mcg/kg/min, these β_1 effects are observed with dosages as low as 3 mcg/kg/min. They seem to be more prevalent in patients who are inadequately resuscitated (hypovolemic), in the elderly, in those with preexisting or concurrent cardiac ischemia or dysrhythmias, and in patients currently receiving other dysrhythmogenic agents, including vasopressors and inotropes.

Dopamine increases PAOP and pulmonary shunting to decrease Pao_2. The increase in PAOP may be due to changes in diastolic volumes from decreased cardiac compliance or increased venous return to the heart by α-adrenergic receptor–mediated venoconstriction. This may affect gas exchange and decrease Pao_2. The increase in pulmonary shunting also may result from acute enhancement of pulmonary blood flow to nonhomogeneous lung regions. Thus, dopamine should be used with caution in patients with elevated preload because the drug may worsen pulmonary edema. In the instance of high filling pressures, tachycardia, or tachydysrhythmias, dopamine should be replaced by another vasopressor and/or inotrope such as norepinephrine, dobutamine, phenylephrine, or epinephrine, depending on the desired effect.

The effect of dopamine on global oxygen-transport variables parallels the hemodynamic effects. Although dopamine improves global Do_2 in septic patients, it may compromise O_2ER in the splanchnic and mesenteric circulations by α_1-mediated vasoconstriction. Splanchnic blood flow and Do_2 increase with dopamine, but with no preferential increase in splanchnic perfusion as a fraction of CO and systemic increases in Do_2. Large doses of dopamine worsen pHi and the Pco_2 gap. This is reflected by a decrease or lack of change in regional Vo_2 and a decrease in tissue O_2ER. Dopamine at low or vasopressor dosages directly impedes gastric motility in critical illness and may aggravate gut ischemia in septic shock. Similar to high-dose administration, low-dose dopamine increases splanchnic blood flow but lowers splanchnic Vo_2 in sepsis. Therefore, dopamine at all dosages impairs hepatosplanchnic metabolism despite an increase in regional perfusion.

The use of dopamine as a first-line agent for septic shock may be questionable because regional hemodynamics, oxygen-transport variables, and functional parameters of improved organ perfusion are not consistently enhanced in a sustained manner and may be negatively impaired.[7,63] The negative findings of low-dose dopamine use (see Low ("Renal") Dose Dopamine above) and the deleterious effects of inotropic and vasopressor dosages of dopamine on regional hemodynamics and oxygen transport raise concern over whether dopamine should be considered the first-line vasopressor agent in patients with severe sepsis or septic shock.[7,7,79] Until dopamine is found to have definitive deleterious clinical outcomes compared to other vasopressors, empirical use of dopamine in a hypotensive patient in whom a pulmonary arterial catheter has not been inserted and in whom the cause of hypotension—low CO or vasodilation—is yet undetermined still may be reasonable. In addition, unlike other vasopressor agents, dopamine is available as premixed ready-to-use solutions of various concentrations that can be stored in automated dispensing systems for rapid initiation.

Norepinephrine

❼ ❾ ❽ ⓭ Use of norepinephrine as first-line therapy may be more rational than dopamine because norepinephrine is more potent and is more effective in increasing MAP.[7,67,68] It has combined strong α_1-activity and less potent β_1-agonist effects while maintaining weak vasodilatory effects of β_2-receptor stimulation.[6–19,49,50,68–76] Several retrospective analyses have demonstrated improved MAP and mortality in ICU patients with severe hypotension treated with norepinephrine either as first-line therapy or after therapeutic failure with fluid resuscitation and dopamine treatment.

Norepinephrine infusions can be titrated to preset goals of MAP (usually at least 65 mm Hg), improvement in peripheral perfusion (to restore urine production or decrease blood lactate), and/or achievement of desired oxygen-transport variables while not compromising the cardiac index. Norepinephrine 0.01 to 2 mcg/kg/min reliably and predictably improves hemodynamic parameters to "normal" or "supranormal" values in most patients with septic shock. As with other vasopressors, norepinephrine dosages exceeding those recommended by most references frequently are needed in critically ill patients with septic shock to achieve predetermined goals. A significant increase in MAP generally is caused by an increase in SVR. In contrast to dopamine, heart rate generally does not increase significantly with norepinephrine because of diminished stimulation of cardiac β_1-receptors in septic shock and reflex bradycardia from increased SVR.[68–76] Increasing norepinephrine doses to maintain higher MAPs may increase heart rates, cardiac index, DO_2, and cutaneous blood flow but these results are inconsistent. Older patients may benefit from the combined α- and β-adrenergic effects of norepinephrine given the higher incidence of coronary disease and compromised ventricles in this patient population. By virtue of restored MAP and hence coronary perfusion, cardiac index is increased in older patients, whereas in younger patients with less coronary artery disease and a higher cardiac index at baseline, norepinephrine acts primarily as a vasopressor. In contrast to dopamine, norepinephrine does not influence PAOP.

The effect of norepinephrine on oxygen transport parameters is variable and depends on baseline values and concurrently administered vasoactive agents. In most studies of norepinephrine alone, either an increase or no change in Do_2 is seen with no change in O_2ER, particularly when Do_2 values were "supranormal" prior to therapy. Norepinephrine demonstrates either no effect or improvement in Pco_2 gap, pHi, or serum lactate concentrations. Splanchnic blood flow and fractional blood flow are higher with norepinephrine than either dopamine or epinephrine despite higher CO with the two latter agents.

Taken together, these data suggest that norepinephrine should be the primary vasopressor of choice in patients in septic shock because of its multiple benefits: (1) norepinephrine may decrease mortality in septic shock; (2) it reverses inappropriate vasodilation and low global oxygen extraction; (3) it attenuates myocardial depression at unchanged or increased CO and increased coronary blood flow; (4) it improves renal perfusion pressure and renal filtration; (5) it enhances splanchnic perfusion; and (6) it is less likely than other vasopressors to cause tachycardias and tachydysrhythmias.[6–19,49,50,68–76]

Phenylephrine

❼ ❽ ❿ ⓭ Despite its purported use in refractory septic shock, little information is available regarding the clinical efficacy of phenylephrine. Nevertheless, it is an attractive agent for use in sepsis because of its selective α-agonism with primarily vascular effects.[6–19,49,50] It is generally initiated at dosages of 0.5 mcg/kg/min and can be titrated every 5 to 15 minutes to desired effects. As with other vasopressors, phenylephrine dosages required to achieve goals of therapy are significantly higher than dosages traditionally recommended for use.

Phenylephrine 0.5 to 9 mcg/kg/min, used alone or in combination with dobutamine or low doses of dopamine, improves blood

pressure and myocardial performance in fluid-resuscitated septic patients. Incremental doses of phenylephrine result in linear dose-related increases in MAP, SVR, heart rate, and stroke index when administered alone as a single agent in stable, nonhypotensive but hyperdynamic, volume-resuscitated surgical ICU patients. In septic shock, phenylephrine does not impair the cardiac index, PAOP, or peripheral perfusion. In sepsis, phenylephrine improves MAP by increasing the cardiac index through enhanced venous return to the heart (increase in CVP and stroke index) and by acting as a positive inotrope. It improves myocardial performance in hyperdynamic, normotensive septic patients but worsens myocardial performance in cardiac controls. In cardiac patients, however, myocardial performance worsens as a result of a decrease in the cardiac index and an increase in SVR. Therefore, phenylephrine use warrants caution in septic shock patients with impaired myocardial performance.

In septic shock, phenylephrine appears to increase global tissue oxygen use, although information regarding the relationship of the oxygen-transport variables with increases in MAP and cardiac index is conflicting. Increases in Vo_2 appear to be dissociated from Do_2, representing an increase in O_2ER as the cardiac index remains unchanged. Increases in Vo_2 may result from redistribution of blood flow to previously underperfused areas, improving oxygen use as a result of changes in MAP and SVR. Evidence of globally improved peripheral tissue perfusion is observed as lactic acid concentration declines or remains unchanged and urine production increases significantly at increased or maximal Vo_2. An increased O_2ER may contribute to improved tissue response.

Few data regarding the effect of phenylephrine on regional hemodynamics and oxygen-transport variables are available. When phenylephrine replaced norepinephrine in patients with septic shock, phenylephrine selectively reduced splanchnic blood flow and thus splanchnic Do_2 and splanchnic lactate uptake rate without changing the overall splanchnic Vo_2. Concomitantly, pHi decreased and arterial lactate concentrations increased. Because all of these parameters normalized when norepinephrine was reinstated, these data suggest that exogenous β-adrenergic stimulation (norepinephrine) may determine hepatosplanchnic perfusion and oxygen availability but not utilization in septic shock. A small study comparing phenylephrine and norepinephrine for initial vasopressor therapy did not demonstrate significant differences between agents with respect to hemodynamic profiles or indices of global and regional perfusion.

The available data on hemodynamics, oxygen-transport variables, and mortality with phenylephrine in septic shock patients may not be generalizable because of the small numbers of patients evaluated. Adverse effects, such as tachydysrhythmias, are notably infrequent with phenylephrine, particularly when it is used as a single agent or at higher doses, because phenylephrine does not exert any activity on β_1-adrenergic receptors. Whether the beneficial effects can be sustained with longer administrations of phenylephrine is unclear. Phenylephrine may be a particularly useful alternative in patients who cannot tolerate tachycardia or tachydysrhythmias with use of dopamine or norepinephrine and in patients who are refractory to dopamine or norepinephrine (because of β-adrenergic receptor desensitization).[7] As with other vasopressors, phenylephrine is continued until resolution of the hemodynamic instability associated with the septic episode and is weaned when patients are clinically stable. Its use in patients with myocardial dysfunction warrants further investigation.

Epinephrine

❼ ❽ ⓫ ⓭ By convention, epinephrine has been reserved as a last-line agent for hemodynamic support of sepsis. Epinephrine, however, may be an acceptable choice as a single agent because of its combined vasoconstrictor and inotropic effects.[7] It is as effective as norepinephrine for blood pressure control. Epinephrine infusion rates of 0.04 to 1 mcg/kg/min alone increase hemodynamic and oxygen-transport variables to "supranormal" values without adverse effects in septic patients without coronary artery disease. Large dosages (0.5–1 mcg/kg/min) often are required. Smaller dosages (0.10–0.50 mcg/kg/min) are effective when epinephrine is added to other vasopressors and inotropes. In addition, younger patients appear to respond better to epinephrine, possibly due to greater β-adrenergic stimulation.

Despite a linear dose–response curve with rapid improvement of hemodynamic variables and Do_2, epinephrine has deleterious effects on regional hemodynamics and oxygen utilization. Although Do_2 increases mainly as a function of increases in the cardiac index and a more variable increase in SVR, Vo_2 may not increase, and O_2ER may fall. A fall in pHi may be seen during epinephrine administration but the impairment in gastric mucosal perfusion can be counteracted in part by dobutamine. This may be explained by the vasodilatory effect of dobutamine on gastric mucosal microcirculation resulting in a redistribution of blood flow toward the mucosa. In contrast to other vasopressors, lactate concentrations frequently rise during epinephrine therapy resulting in variable arterial pH values. When compared with a combination of norepinephrine and dobutamine, epinephrine preferentially decreases splanchnic Do_2, worsens pHi, and increases systemic lactate concentration without increasing Vo_2. The effects of epinephrine on absolute and fractional splanchnic blood flow are more pronounced during severe shock. The increase in lactate may be a result of worsened Do_2 to the liver (and subsequent anaerobic metabolism) or to the hepatosplanchnic circulation, direct increase in calorigenesis and breakdown of glycogen, or lactate mobilization. However, evidence suggests that epinephrine, in contrast to dopamine, increases the proportion of total CO delivered to the splanchnic circulation, although Vo_2 is not increased sufficiently. As a result, O_2ER values are usually lower with epinephrine than with other vasopressors but the concomitant administration of dobutamine helps maintain O_2ER. Of all the vasopressors, epinephrine exhibits the most pronounced capacity to induce hyperglycemia by increased gluconeogenesis and glycogenolysis with α-mediated suppression of insulin secretion.[49,50]

Despite the administration of high doses, epinephrine-associated clinically important dysrhythmias or cardiac ischemia occur at variable rates irrespective of age or underlying cardiac status.[6–19,49,50,75,76] Nevertheless, caution must be exercised before considering epinephrine for managing hypoperfusion in hypodynamic patients with coronary artery disease, in whom ischemia, chest pain, or myocardial infarction may result. Based on the current evidence, epinephrine should not be used as initial therapy in patients with septic shock refractory to fluid administration.[7] Although it effectively increases CO and Do_2, it has deleterious effects on the splanchnic circulation. If it is used as a second-line agent in septic shock, factors that may influence successful therapy with epinephrine include the time from onset of septic shock to effective therapy and the age of the population.

Dobutamine

❻ ❼ ⓬ ⓭ Dobutamine is an inotrope with vasodilatory properties (an "inodilator").[6–19,49,50] It is used for treatment of septic and cardiogenic shock to increase the cardiac index, typically by 25% to 50%.[7] In septic shock, LVEF and right ventricular function are depressed despite a high cardiac index, whereas ventricular volumes and compliance are increased. Stroke index is maintained by an increased heart rate and ventricular dilation. In survivors, myocardial depression is reversible and normalizes 5 to 10 days after the onset of sepsis. Dobutamine increases stroke index, left ventricular stroke work index, and thus cardiac index and Do_2 without increasing

PAOP.[7] The ability of dobutamine to enhance cardiac index and Do_2 during septic shock appears to be related to its chronotropic effect. However, dosage increments of dobutamine beyond 20 mcg/kg/min are limited by complications of tachycardia, ischemic changes on electrocardiogram, hypertension, and tachydysrhythmias despite the absence of preexisting cardiac abnormalities. Of note, the combination of dobutamine and norepinephrine results in a lower increase in heart rate compared with use of other vasopressors alone.

Increased cardiac performance measures in response to adjunctive dobutamine therapy are predictive of survival during sepsis. However, the achievement of supranormal oxygen transport values with dobutamine is of little value compared with treatment to normal values. In addition, administration of dobutamine to achieve these high values may increase mortality rate and/or the incidence of adverse effects. Dobutamine increases Do_2 without affecting Vo_2, resulting in decreased O_2ER. Arterial lactate concentrations decrease significantly with norepinephrine and dobutamine compared with dopamine and epinephrine infusions.

Studies have focused on the effects of dobutamine on gastric mucosal flow and the splanchnic circulation. The addition of dobutamine to other vasopressors improves gastric mucosal perfusion without increasing the cardiac index. This is consistent with findings that dobutamine may improve pHi and mucosal perfusion in septic patients. The addition of dobutamine to norepinephrine or epinephrine treatment improves gastric mucosal perfusion as measured by improvements in pHi, and Pco_2 gap. This effect may relate to blood flow redistribution toward gastric mucosa, due to either an increase in the fraction of CO distributed to the global hepatosplanchnic blood flow and/or a redistribution of blood flow within gastric wall layers toward the mucosa by "stealing" blood away from the muscularis potentially as a result of greater β_2-mediated vasodilation. Sublingual microcirculation improves after dobutamine is added to vasopressor-dependent septic shock patients in a manner unrelated to arterial pressure or cardiac index, suggesting that enhanced perfusion is the result of the "steal" phenomenon. Of note, gastric mucosal perfusion and tissue oxygen utilization are most improved with concurrent norepinephrine and dobutamine therapies compared with other vasopressor combinations at the same level of MAP.

Dobutamine should be started at dosages ranging from 2.5 to 5 mcg/kg/min. In the study of early goal-directed therapy, dobutamine was administered to 13.7% of patients within 6 hours of resuscitation to achieve $Scvo_2$ ≥70%.[30] Although a dose response may be seen, evidence now suggests that dosages >5 mcg/kg/min may provide limited beneficial effects on oxygen transport values and hemodynamics and may increase adverse cardiac effects. If given to patients who are intravascularly depleted, dobutamine will result in hypotension and a reflexive tachycardia. Pathophysiologic factors influence dosing requirements and pharmacokinetic parameters over the time course of the illness and the duration of the infusion. Decreases in Pao_2, as well as myocardial adverse effects such as tachycardia, ischemic changes on electrocardiogram, tachydysrhythmias, and hypotension are seen. Thus, infusion rates should be guided by clinical end points and Svo_2/$Scvo_2$. Dobutamine, like other inotropes, usually is given until improvement in myocardial function with resolution of the septic episode or dose-limiting side effects are observed.

Vasopressin

14 Studies involving vasopressin infusion for management of septic shock show rapid and sustained improvement in hemodynamic parameters.[51–53,64] These effects are evident with administration of dosages not exceeding 0.04 units/min. Administration of dosages >0.04 units/min and 0.05 units/min are associated with negative changes in CO and mesenteric mucosal perfusion, respectively. The reduction in CO likely is the result of lowered stroke volume.[51–53] The studies that reported cardiac function indicate patients had adequate CO prior to initiating vasopressin therapy. Therefore, vasopressin use in septic shock patients with cardiac dysfunction warrants extreme caution. Cardiac ischemia appears to be a rare occurrence and may be related to administration of dosages ≥0.05 units/min.

Mesenteric ischemia associated with vasopressin may be clinically relevant. Increased hepatic transaminases and total bilirubin concentrations may occur with vasopressin therapy, suggesting impaired hepatic blood flow or a direct effect on excretory hepatic function.[51–53] Most studies have found that vasopressin at dosages of 0.04 to 1.8 units/min worsen pHi or Pco_2 gap when it is added to low or high doses of catecholamine vasopressors.[51–53] Mesenteric mucosal hypoperfusion may be expected with vasopressin because mesenteric vasoconstriction occurs at vasopressin serum concentrations as low as 10 pg/dL, and the effect is dose dependent. Of concern is the additive effective with norepinephrine despite substantially reduced dosages of norepinephrine when vasopressin is initiated. Although controversial, the degree of hypoperfusion with vasopressin may be greater than with norepinephrine alone unless the dose of norepinephrine is markedly increased to maintain adequate arterial blood pressure.

Vasopressin's strongest vasoconstrictive action occurs in the skin and soft tissues, skeletal muscles, and fat tissues.[51–53] As a result, ischemic skin lesions have been observed in several studies, with an occurrence rate as high as 30% after vasopressin was added to norepinephrine-resistant shock. Although vasopressin may have deleterious effects on mesenteric and skin perfusion, studies report vasodilation of cerebral, pulmonary, coronary, and some renal vasculature beds. The clinical outcomes associated with selective vasodilation are not yet determined except for the possibility of enhanced urine production in patients not anuric at baseline.

In order to minimize the potential for adverse events and maximize the beneficial effects, vasopressin should be used as add-on therapy to one or two catecholamine adrenergic agents rather than as first-line therapy or salvage therapy and dosages should be limited to 0.04 units/min.[7,51–53] The results of studies showed that vasopressin markedly reduced the requirements for adrenergic agents, but few studies demonstrated complete discontinuation of these therapies.[51–53,64] Therefore, vasopressin should be used only if response to one or two adrenergic agents is inadequate or as a method for reducing the dosage of these therapies. Increased arterial pressure should be evident within the first hour of vasopressin therapy, at which time the dose(s) of adrenergic agent(s) should be reduced while maintaining blood pressure. This method should help limit the degree of ischemia.

Most studies evaluated vasopressin use for <48 hours, and several studies reported difficulty discontinuing vasopressin therapy. Whether additional benefits, deleterious effects, or tolerance is observed with longer infusions remains unclear. Long-term administration of vasopressin is associated with hyponatremia and thrombocytopenia. Because vasopressin is being used to replace a physiologic deficiency, it stands to reason that the requirement for vasopressin will subside with reversal of the septic process. Attempts to discontinue vasopressin should occur when the dosage(s) of adrenergic agent(s) has been minimized (e.g., dopamine ≤5 mcg/kg/min, norepinephrine ≤0.1 mcg/kg/min, phenylephrine ≤1 mcg/kg/min, epinephrine ≤0.15 mcg/kg/min). At present, vasopressin should not be initiated as first-line therapy or added to existing therapy solely because a patient is septic.

Corticosteroids

14 Corticosteroids can be initiated in cases of septic shock when adrenal insufficiency is present or when weaning of vasopressor therapy proves futile.[54,62] Adverse events are few because corticosteroids are administered for a finite period of time, usually 7 days.

Acutely, elevated serum concentrations of blood urea nitrogen, white blood cell count, and glucose occur. Although long-term administration of corticosteroids is associated with several chronic disease states, meta-analyses do not show an increase in adverse events, including gastrointestinal hemorrhage (RR, 1.12; 95% CI, 0.81–1.53; $P = 0.5$), superinfections (RR, 1.01; 95% CI, 0.82–1.25; $P = 0.92$), and neuromuscular weakness (RR, 0.63; 95% CI, 0.12–3.35; $P = 0.58$).[55,56] Hyperglycemia (RR, 1.16; 95% CI, 1.07–1.25; $P < 0.001$) and hypernatremia (RR, 1.61; 95% CI, 1.26–2.06; $P < 0.001$) are associated with corticosteroid therapy.[55,56] Therefore, therapy of septic shock with corticosteroids improves hemodynamic variables and lowers catecholamine vasopressor dosages with minimal to no effect on patient safety.[7]

EXPERIMENTAL THERAPIES

NITRIC OXIDE INHIBITORS

NO is a short-acting, potent vasodilator derived from enzymatic oxidation of arginine. Its production is under control of NOS. This enzyme is present (expressed) in two forms: a constitutive form (ecNOS) and an inducible form (iNOS). Small amounts of NO normally are produced by the vascular endothelium under the control of ecNOS for physiologic control of vascular tone and blood flow distribution. Under pathophysiologic conditions such as stimulation by lipopolysaccharide or cytokines, iNOS becomes diffusely expressed, producing large amounts of NO. The latter has been implicated in the cardiovascular failure of septic shock.

Pharmacologic inhibition of NO production has been investigated as an adjunct to standard therapies of septic shock. L-Arginine analogs such as monomethyl-L-arginine (L-NMMA) and L-arginine-methylester (L-NAME) are competitive inhibitors of NOS and have been shown to increase blood pressure, partially restore vascular reactivity, and reduce vasopressor use.[7,11,12] However, because these arginine analogs nonselectively block ecNOS and iNOS, their use has been associated with extensive vasoconstriction, decreased CO, and regional hypoperfusion, thus promoting organ failure and mortality. Some *S*-substituted thiourea derivatives have demonstrated, both in vitro and in vivo (rodent), dose-dependent selectivity for iNOS inhibition, but the clinical application must be evaluated. A phase I/IIa clinical trial of septic shock patients is underway (see *www.medinox.com*).

Pyridoxalated hemoglobin polyoxyethylene is a scavenger of NO. A phase II study of 62 patients with vasodilatory shock requiring vasopressors showed that an infusion of 20 mg/kg/h for up to 100 hours rapidly increases blood pressure and shortens the duration of vasopressor therapy.[82] Additional studies are needed.

METHYLENE BLUE

Methylene blue counteracts ecNOS, iNOS, and soluble guanylate cyclase to reduce serum concentrations of NO and cyclic guanosine monophosphate.[83] Despite these effects, methylene blue does not alter the expression of inflammatory cytokines. Clinically, methylene blue at dosages of 0.25 to 3 mg/kg/h increases SVR, MAP, myocardial contractility, and DO_2 in septic shock patients refractory to vasopressors.[83] It may increase pulmonary vascular resistance, potentially worsening oxygenation. Additional studies are needed before methylene blue can be recommended; at present, it has been used only for salvage therapy.

TERLIPRESSIN

Terlipressin, a prodrug that is converted into lysine vasopressin, has been used in septic shock patients and is available in other countries.[84] This drug has a half-life of 6 hours and acts via vascular V_1 receptors and renal tubular V_2 receptors. Terlipressin increases MAP to a greater extent than norepinephrine when it is used as the initial vasopressor in septic shock. Despite a decrease in CO, heart rate, and Do_2I, terlipressin increases gastric mesenteric perfusion, urine production, and creatinine clearance while reducing lactate concentration. Both terlipressin and vasopressin increase blood pressure and decrease heart rate to the same extent but terlipressin is associated with less supplemental norepinephrine usage and improved mesenteric perfusion.[85,86] These preliminary findings suggest that a clinical trial evaluating mortality as well as hemodynamic effects should be conducted.

LEVOSIMENDAN

Levosimendan is a novel inotropic and vasodilator calcium-sensitizing drug.[87] In acute decompensated heart failure, it improves cardiac contractility by sensitizing troponin C to calcium. In septic shock patients with and without left ventricular dysfunction, levosimendan 0.1 to 0.2 mcg/kg/min decreases PAOP, increases LVEF and cardiac index, improves mesenteric perfusion, and enhances urine production.[87] Levosimendan improves $ScvO_2$ to the same extent as dobutamine when it is used in early goal-directed therapy. Levosimendan is associated with declining serum lactate concentration. While additional clinical trials of levosimendan in septic shock are needed, increased mortality was demonstrated in studies of acute decompensated heart failure.

DOPEXAMINE AND ISOPROTERENOL

Dopexamine is a structural and synthetic analog of dopamine that exerts systemic vasodilation through stimulation of β_2-adrenoceptors and peripheral D_1 and D_2 receptors and weak inotropic properties through stimulation of β_1-adrenoceptors.[49,50] It has been used in patients with acute heart failure and septic shock. Similar to dobutamine, dopexamine is administered in combination with a vasopressor in septic shock. In small studies of septic shock, dopexamine produced a dose-related (range, 2–6 mcg/kg/min) increase in cardiac index, stroke volume, and heart rate, as well as a decrease in SVR over the course of 0.5 to 1 hour while the dosages of other vasopressors were kept constant. The increase in myocardial oxygen demand is less than with dopamine, but tachycardia and tachydysrhythmia may lead to myocardial ischemia, especially when ischemic heart disease is present. Global oxygen-transport variables are similar to those of dopamine: Do_2 increases but Vo_2 increases insufficiently, resulting in impaired O_2ER. The combined β_2-adrenoceptors and peripheral D_1 agonistic effects of dopexamine should improve distribution of blood flow. However, the results of studies of dopexamine use in septic shock failed to show preferential increase in splanchnic blood flow. In fact, gastric pHi was lowered. When administered over 7 days, dopexamine had no impact on renal function. Therefore, initial data do not support a role for dopexamine in improving regional hemodynamics and blood flow, but studies continue to investigate dopexamine as an alternative therapy for septic shock.

Isoproterenol is a synthetic catecholamine that stimulates only β_1-and β_2-adrenoceptors to produce vasodilatory and inotropic effects.[88] Although not thought of as a traditional agent for managing septic shock, isoproterenol has received attention because of the concepts of early goal-directed therapy.[30] The strong β-adrenergic effects of isoproterenol make it a potential alternative to dobutamine for optimizing Do_2 in patients with low Svo_2 despite use of other therapies (e.g., fluid resuscitation, vasopressors, red blood cell transfusion). In patients with septic shock and Svo_2 <70% despite volume administration, norepinephrine, and red blood cell transfusion, adding isoproterenol increases Svo_2, cardiac index, and stroke

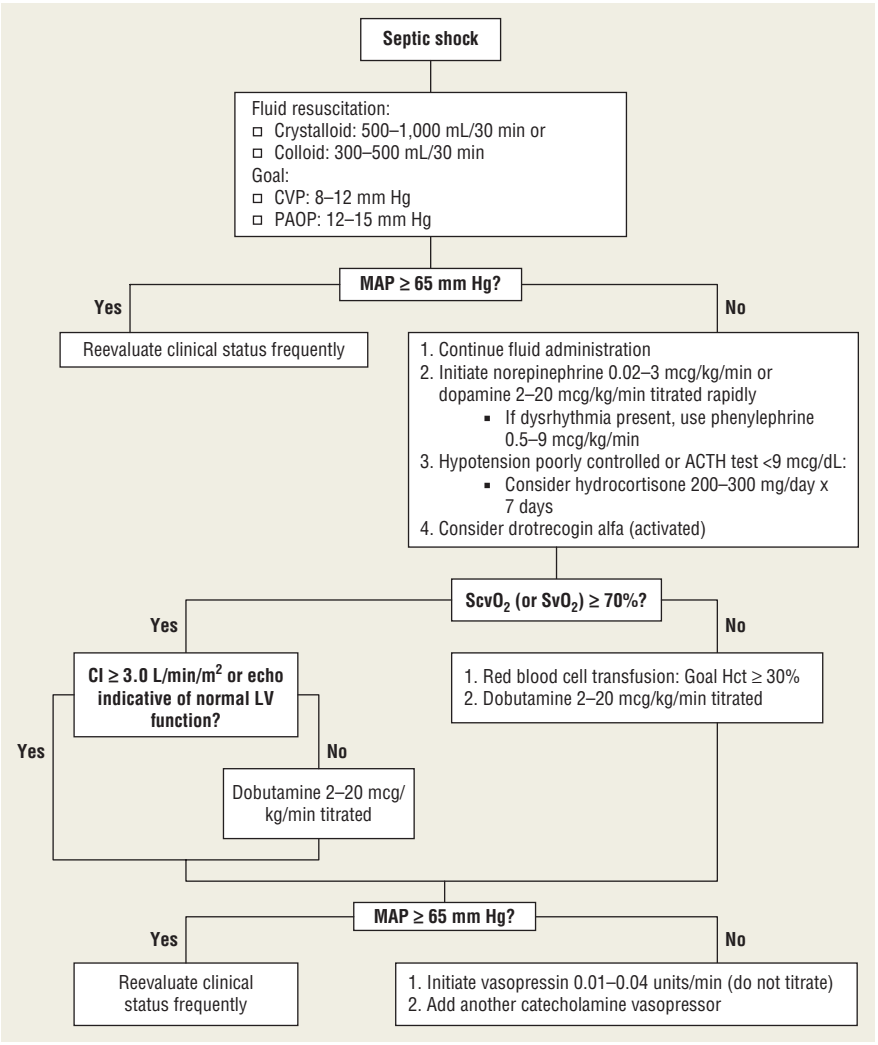

FIGURE 30-2. Algorithmic approach to resuscitative management of septic shock. Algorithmic approach is intended to be used in conjunction with clinical judgment, hemodynamic monitoring parameters, and therapy end points, as discussed in the text. (ACTH, adrenocorticotropic hormone; CI, cardiac index; CVP, central venous pressure; echo, echocardiography; Hct, hematocrit; MAP, mean arterial pressure; PAOP, pulmonary artery occlusive pressure; $Scvo_2$, central venous oxygen saturation; Svo_2, mixed venous oxygen saturation.) (*Figure based on data from references 6–19, 49–65.)*

index while decreasing lactate concentration without increasing heart rate or causing myocardial ischemia. Although these results are intriguing, additional studies are needed to define the role of isoproterenol, especially considering that dobutamine has become standard therapy for early goal-directed therapy. At present, isoproterenol is an agent of last resort.

OTHER THERAPIES

As with vasopressin and cortisol, critical illness impairs hypothalamic–pituitary function, producing relative deficiencies of triiodothyronine (T_3) and thyroxine (T_4). This condition, referred to as *euthyroid sick syndrome*, may contribute to hypotension.[89] Concentrations of thyrotropin-releasing hormone and thyroid-stimulating hormone are inappropriately low. Measured concentrations of free T_3 and T_4 may be low or normal, but synthesis is consistently impaired. Only scant data regarding the replacement of these hormones in critically ill patients are available, and the results are variable, depending on the extent of additional hormone replacement (growth hormone, gonadotropin-releasing hormone, leptin, insulin, thyrotropin-releasing hormone, and thyroid-stimulating hormone). Given the data for replacing vasopressin and cortisol in septic shock, it is reasonable to assume that one day a "thyroid replacement" regimen will be offered as an adjunctive treatment to vasopressors.

Drotrecogin alfa (activated) or recombinant activated protein C has been established as a treatment of severe sepsis because it reduces mortality when used early in patients with at least two organ dysfunctions or an Acute Physiology and Chronic Health Evaluation (APACHE) II score of 25.[90] Drotrecogin alfa (activated) promotes fibrinolysis, inhibits coagulation, and modulates inflammation. It inhibits inflammation, possibly preventing endotoxin-induced hypotension. A study of 22 septic shock patients treated with drotrecogin alfa (activated) showed that the norepinephrine dosage rate decreased 33% over 24 hours.[91] In contrast, the norepinephrine dosage increased 38% in the matched control group despite MAP values similar to the drotrecogin alfa (activated) group. Although these results deserve further investigation, drotrecogin alfa (activated) likely will never be administered solely for hemodynamic support of septic shock patients because it is an expensive agent with concerns of hemorrhage as a side effect. Ultimately, patients who "qualify" for drotrecogin alfa (activated) will receive it irrespective of hemodynamic effect.

GENERAL CONCLUSIONS AND RECOMMENDATIONS

The choice of vasopressor or inotropic agent in septic shock should be made according to the needs of the patient. Figure 30–2 presents an algorithm for the management of septic shock.[6–19,49–65] This algorithm suggests a stepwise approach, first using dopamine or norepinephrine. Dobutamine is added for low CO states or to optimize Svo_2/$Scvo_2$. Occasionally, epinephrine and phenylephrine are used when necessary. Although this approach is empirical, it is used

broadly in clinical practice and has been justified by the desire to avoid strong vasoconstriction. However, observations of improved outcomes with norepinephrine and decreased regional perfusion with dopamine are calling into question the use of dopamine as a first-line agent. Most clinicians now prefer norepinephrine as the initial vasopressor agent. Developing a strategy to titrate therapy early in the course of illness to predetermined values reduces mortality. Goals of initial resuscitation should include fluids to achieve CVP 8 to 12 mm Hg, vasopressor agents to achieve MAP at least 65 mm Hg, red blood cell transfusion to maintain hematocrit ≥30%, and inotropic therapy to achieve $Scvo_2$ ≥70%.[7,30] For all catecholamine vasopressors, doses higher than recommended traditionally are required for goal-directed therapy to MAP and for normalization of oxygen-transport variables, Do_2, and Vo_2. Patients who develop supranormal Do_2 and Vo_2 values have lower mortality, but whether this effect is achieved intrinsically or with exogenous administration of vasopressors/inotropes appears inconsequential. Therefore, goal-directed therapy to supranormal oxygen-transport variables cannot be recommended because little or no benefit has been demonstrated. Further work is required to better elucidate the differential effects of vasopressors on regional hemodynamic and oxygen-transport values as measures of local tissue perfusion.

The algorithmic approach (Fig. 30–2) we recommend for use of vasopressors and inotropes in the hemodynamic support of critically ill septic patients is consistent with the recommendations made in the Surviving Sepsis Campaign[7] and the American College of Critical Care Medicine's guidelines to the hemodynamic support of adult patients with sepsis (Table 30–2).[6,8] Although difficult to demonstrate, true differences in clinical outcomes as a result of differences in the pharmacologic activity of vasopressors and inotropes may exist. For example, evidence suggests that norepinephrine, when used appropriately with fluid replenishment, is safe and effective in treating septic shock; it decreases mortality, particularly when started early in the course of septic shock. It is effective in optimizing hemodynamic variables and improving systemic and regional (e.g., renal, gastric mucosal, and splanchnic) perfusion. Epinephrine causes a greater increase in the cardiac index and Do_2 and increases gastric mucosal flow but may not preserve splanchnic circulation adequately. It may cause increases in lactic acid. Epinephrine may be particularly useful when used earlier in the course of septic shock in young patients. Unlike epinephrine, dopamine does not increase the proportion of CO that preferentially goes to the splanchnic circulation. The ability of dopamine to increase CO by no more than 35% accompanied by a tachycardia or tachydysrhythmias limits its utility. Dopamine, as opposed to norepinephrine, has been shown to worsen splanchnic Vo_2 and O_2ER and is of limited value in improving urine production. Low-dose dopamine has not been shown consistently to increase the glomerular filtration rate, does not prevent renal failure, and actually worsens splanchnic tissue oxygen utilization. Low-dose dopamine should not be used. Phenylephrine should be used when a pure vasoconstrictor is desired in patients who may not require or cannot tolerate the β-effects of dopamine or norepinephrine with or without dobutamine. In patients with a high filling pressure and hypotension, the combination of phenylephrine and dobutamine may be useful.

Shortcomings of study methodology prevent the establishment of definitive conclusions. As a consequence, published guidelines for the management of severe sepsis and septic shock have many inconclusive recommendations (Table 30–2). Short infusions during studies may show differences that are not clinically significant after 24 hours, as demonstrated for epinephrine and dobutamine. Clinically, vasopressors and inotropes are used for hours to days. Possible confounding factors are the variable times at which studies are initiated with respect to the stage of sepsis or septic shock, the inherent differences in circulating catecholamine concentrations, changes in receptor activity, as well as differences in prestudy duration and type of exogenous catecholamine administration.

Initial studies with vasopressin suggest a potential role in the management of vasopressor-dependent septic shock patients. Vasopressin appears to reduce the requirements of adrenergic agents while maintaining hemodynamic function. While it may enhance urine production, it is associated with mesenteric and peripheral ischemia. Therefore, vasopressin should be used only if response to one or two adrenergic agents is inadequate or as a method for reducing the dosage of these therapies. Close monitoring of ischemic events is needed. Data indicate that moderate doses of hydrocortisone (200–300 mg/day) administered over several days may reverse septic shock and dependency on vasopressor agents, particularly in patients with relative adrenal insufficiency. As a result of a recent multicenter study, the presence of adrenal insufficiency to indicate therapy with corticosteroids is controversial. Given the discrepancy of the current data, corticosteroids may be administered to patients with septic shock refractory to vasopressors or when adrenal insufficiency is present. Data on optimal dosage regimens and definitive outcomes still are needed.

Further pharmacotherapeutic and outcomes studies are required to elucidate the place in therapy of individual vasopressors and inotropes or their combinations in the supportive care of patients with bacteremia or septic shock. As supportive therapy, it is imperative that primary therapy aimed at the source of (antimicrobials) and consequences of (anticytokines) infection be initiated quickly to afford the patient the best chance of survival. Once this goal is accomplished, we will need to direct our efforts to pharmacoeconomics and the cost effectiveness of these therapies.

ABBREVIATIONS

ACTH: adrenocorticotropic hormone
APACHE: Acute Physiology and Chronic Health Evaluation
ATP: adenosine triphosphate
CaMK: calcium-calmodulin-dependent protein kinase
cAMP: cyclic adenosine monophosphate
Cao_2: arterial oxygen content
CI: confidence interval
CO: cardiac output
CO_2: carbon dioxide
Cvo_2: venous oxygen content
CVP: central venous pressure
Do_2: oxygen delivery
DO_2I: oxygen delivery index
ecNOS: constitutive nitric oxide synthase
HR: hazard ratio
ICU: intensive care unit
IL: interleukin
iNOS: inducible nitric oxide synthase
L-NAME: L-arginine-methylester
L-NMMA: monomethyl-L-arginine
LVEF: left ventricular ejection fraction
MAP: mean arterial pressure
NO: nitric oxide
NOS: nitric oxide synthase

O_2ER: oxygen extraction ratio
OR: odds ratio
$Paco_2$: arterial carbon dioxide pressure (tension)
Pao_2: arterial oxygen pressure (tension)
PAOP: pulmonary artery occlusion pressure
Pco_2: gut luminal partial pressure of carbon dioxide
pHi: intramucosal pH
PLC: phospholipase
$Pslco_2$: sublingual carbon dioxide pressure
RR: relative risk
Sao_2: arterial oxygen saturation
$Scvo_2$: central venous oxygen saturation
Svo_2: mixed venous oxygen saturation
SVR: systemic vascular resistance
T_3: triiodothyronine
T_4: thyroxine
TNF: tumor necrosis factor
Vo_2: oxygen consumption
Vo_2I: oxygen consumption index

CHAPTER 31

Hypovolemic Shock

BRIAN L. ERSTAD

KEY CONCEPTS

1. Plasma does not have to be lost from the body for hypovolemic shock to occur.
2. Patients may die of hypovolemic shock despite having normal serum electrolyte concentrations.
3. Although the Starling equation of fluid transport is useful for understanding the factors involved in fluid shifting between compartments, it is not a practical tool for use in the clinical setting.
4. Patients may have complications and death as a result of reperfusion injury as well as the initial insult.
5. The clinical presentation of patients with hypovolemic shock can vary substantially, depending on concomitant disease states, medications, and cause of hypovolemia.
6. The initial monitoring of a patient with suspected intravascular depletion always should include vital signs, urine output, mental status, and physical examination.
7. The need for intravenous (versus oral) rehydration in children often is overestimated.
8. Crystalloid (sodium-containing) solutions should be used for most forms of circulatory insufficiency that are associated with hemodynamic instability.
9. Neither crystalloids nor colloids have the oxygen-carrying properties of red blood cells.
10. Vasoactive medications should not be considered for hypovolemic shock until fluid resuscitation has been optimized.

This chapter discusses the assessment and management of hypovolemic shock. Neurogenic shock resulting from loss of sympathetic activity and anaphylactic shock resulting from increased vascular permeability often are considered separately from hypovolemic shock because fluid loss from the body is not necessary for their occurrence. Although these forms of shock are not discussed in detail, it is important to note that intravenous fluid administration (in conjunction with vasoactive medications) is a mainstay of therapy because circulating volume is decreased. In this regard, adequate fluid resuscitation to maintain circulating blood volume is a common principle in managing all forms of shock.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

EPIDEMIOLOGY

Because shock is not a reportable category by state and federal agencies that track causes of death, the incidence is unknown. Estimates of deaths due to shock are complicated by differences in definitions and classification systems. Part of the problem is defining when progressive circulatory insufficiency results in the loss of normal compensatory responses by the body, which could reverse the processes leading to irreversible organ dysfunction. This loss of appropriate compensation varies from patient to patient and is not always readily apparent during the initial patient presentation. Therefore, forms of hypovolemic shock, such as hemorrhagic shock, are subsumed by more readily identifiable categories of death, such as accidental injuries and homicides. Crude and conservative estimates of death due to hypovolemic shock are available for some of its forms. More than 100,000 deaths each year in the United States are due to unintentional injuries that frequently involve bleeding,[1] and approximately 5,000 deaths are due to hyperthermia and dehydration associated with heat exposure.[2] The figures are much higher when considered on a global basis. For example, electrolyte depletion and dehydration due to diarrheal disease result in approximately 2 million deaths each year in children younger than 5 years.[3] The most liberal estimates of death include all causes of circulatory failure (i.e., the last stage of shock).

ETIOLOGY

1. Hypovolemic shock may result from blood loss (plasma and red blood cells) due to trauma, surgery, or internal hemorrhage or from plasma loss due to fluid sequestered within the body or lost from the body (Table 31–1). In some cases, such as in

TABLE 31-1 Causes of Hypovolemic Shock[a]

Decreased blood (plasma + red blood cells) volume
External: Surgery or trauma
Internal (e.g., cerebral, chest, gastrointestinal and other abdominal sources, long bone fractures, retroperitoneum)
Decreased plasma volume
External: Losses from urine, gastrointestinal tract (e.g., vomiting, nasogastric suctioning, fistula, diarrhea), lungs, or skin (including thermal injury)
Internal (decreased oncotic pressure or increased capillary permeability): fluid accumulation in bowel, peritoneal or pleural cavities

[a]Shock may result from various combinations of blood and plasma volume losses listed (i.e., causes are not mutually exclusive).

postoperative patients, a number of these problems occur at the same time. For example, a patient may have blood loss secondary to trauma or surgery, with additional fluid being third spaced (e.g., as tissue edema in the gastrointestinal tract with a concomitant ileus) and lost through a high-output gastrointestinal fistula postoperatively. As this example of third-spaced fluid indicates, fluid (i.e., plasma) does not have to be lost from the body for a person to develop hypovolemic shock, although the fistula output would clearly aggravate the situation. Approximately 20 L of fluid is secreted and reabsorbed daily in the gastrointestinal tract, so it is not surprising that volume loss could be substantial, depending on the location of the fistula and function of the tract preceding the fistula.

Dehydration may result from primary water deficiency, usually because of decreased intake, but in some instances (e.g., diabetes insipidus) may result from increased losses of water. With most forms of dehydration, such as those caused by diarrheal disease and heat-related illness, a combination of inadequate intake and higher than normal losses occurs. In general, the term *dehydration* implies primary intracellular water depletion, in contrast to *volume depletion*, which implies extracellular, and particularly intravascular, sodium and water loss. However, there is substantial overlap in the definitions and use of terms such as *dehydration* and *volume depletion* in the medical literature, so the reader must be cognizant of the intended meaning. In the case of primary water deficit, cell dehydration occurs. Initially, the patient may be thirsty and possibly have some mental status changes, such as confusion. If cellular dehydration occurs slowly, intracellular substances, referred to as *idiogenic osmols*, develop that limit progressive complications (e.g., cerebral edema or coma). Death due to primary water deficit, if it occurs, is usually a result of delayed circulatory failure. With combined water and salt deficiencies, such as might occur with gastrointestinal (e.g., diarrhea) and skin losses (e.g., heat stroke), interstitial and intravascular depletion is an early occurrence. Fortunately, dehydration is relatively easy to prevent with routine vigilance and water replacement compared with some of the other causes of shock.

PATHOPHYSIOLOGY

2 Hypovolemic shock often is described in terms of monitoring parameters such as lowered blood pressure, but patients with shock may die despite normal surrogate markers of circulatory insufficiency. Therefore, an appropriate definition should mention the underlying problem, which is inadequate tissue perfusion resulting from circulatory failure. In the case of hypovolemic shock, the cause of the altered perfusion is fluid (or volume) depletion resulting from trauma, surgery, thermal injury, or some form of dehydration. Figure 31–1 provides a simplified view of the pathophysiology of circulatory insufficiency assuming the acute insult causing the plasma volume depletion did not result in immediate patient death. Cell damage and death may occur from the primary insult or from reperfusion injury. The latter problem is associated most frequently with trauma and blood loss that cause a systemic inflammatory response syndrome (SIRS) with the release of a multitude of mediators of inflammation and injury that have complex interactions. Cells have varying responses to hypoxia, ranging from astrocytes that quit functioning almost immediately to hepatic cells that may function for several hours after injury to skin, muscle, and bone cells that may tolerate prolonged periods of hypoperfusion.[4,5] Left unmitigated, cell death occurs with prolonged injury and is usually heralded by acidosis, hypothermia, and coagulopathy—referred to as the lethal triad.[5]

The body attempts to compensate for volume depletion beginning with autoregulatory changes involving smaller blood vessels. When the cause of circulatory insufficiency continues unabated, local mechanisms eventually fail to provide adequate compensation, and macrocirculatory changes ensue. Approximately 75% of blood volume is contained in venous capacitance vessels, with gravity being the major impedance to flow back to the heart.[4] With increasing volume depletion, blood flow to the heart (preload) is decreased, with subsequent activation of baroreceptors and chemoreceptors leading to sympathetic discharge. Also, fluid shifting from the interstitial space to the intravascular space occurs through a phenomenon known as *transcapillary refill*, and hormones (e.g., adrenocorticotropic hormone, angiotensin, catecholamines, and vasopressin) that cause sodium and water retention by the kidneys are released. The phenomenon of transcapillary refill means that the body can have fluid losses exceeding normal plasma volume. These responses cause alterations in stroke volume, heart rate, and peripheral vascular resistance so that blood pressure and hence tissue perfusion can be maintained.

The microcirculatory changes associated with shock are complex and difficult to study. Although some mediators such as catecholamines, angiotensin II, arginine vasopressin, and endothelin-1 cause vasoconstriction, other mediators, such as adenosine and nitric oxide, yield vasodilation. These changes result in hypoperfusion or hyperperfusion, depending on the organs involved. As these microcirculatory changes fail to maintain adequate organ

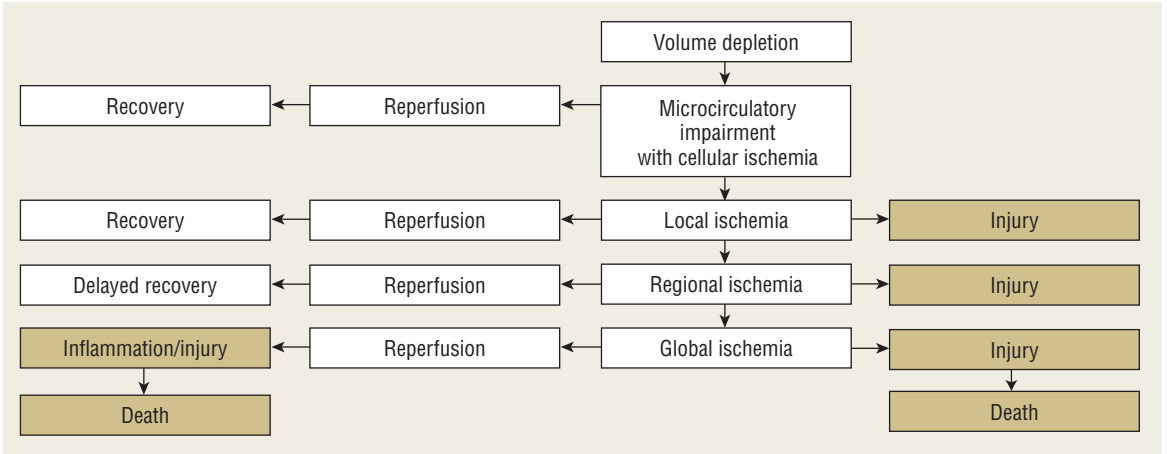

FIGURE 31-1. Pathophysiology of circulatory insufficiency.

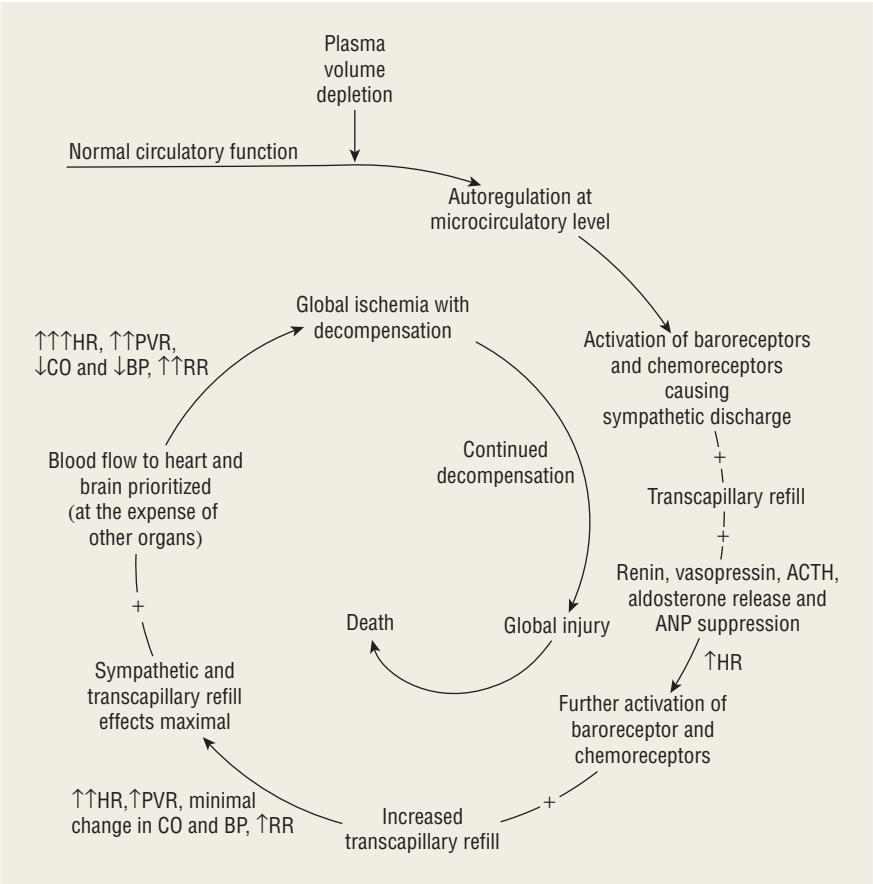

FIGURE 31-2. Activation of compensatory mechanisms with loss of circulatory volume. Certain stages may be absent, depending on a number of factors, such as age, preexisting disease states, and cause of circulatory insufficiency. (ACTH, adrenocorticotropin; BP, blood pressure; CO, cardiac output; HR, heart rate; PVR, peripheral vascular resistance; RR, respiratory rate.)

perfusion, more widespread sympathetic nervous system activation and vasoconstriction ensue. Even assuming general circulation is restored, capillaries may not function properly due to ongoing edema and ischemia. Failure to respond to sympathetic stimulation and fluid administration is indicative of the vasodilation that occurs in the final phase of circulatory failure leading to death.

The factors involved in fluid shifting between the intravascular and interstitial spaces are described by the modified Starling equation:

$$J_v = K_{f,c}[(P_c - P_t) - [\sigma(\pi_c - \pi_t)]$$

where J_V = net transvascular flow rate (cannot be measured in the clinical setting)

$K_{f,c}$ = capillary filtration coefficient for fluids (cannot be measured in the clinical setting)

P_c = capillary hydrostatic pressure (indirectly estimated in the clinical setting, e.g., pulmonary artery occlusive pressure)

P_t = tissue hydrostatic pressure (cannot be measured in the clinical setting)

σ = reflection coefficient for proteins (cannot be measured in the clinical setting)

π_c = plasma colloid osmotic pressure (not usually measured in the clinical setting, but technology is available)

π_t = tissue colloid osmotic pressure (cannot be measured in the clinical setting)

Proteins act as oncotic agents in each of these spaces to attract fluid, whereas hydrostatic forces push fluid into or out of the vessels. The equation has distinct permeability values for water and protein because each crosses the vascular membrane at a different rate. The values for the variables listed in the equation are not the same for capillaries in all parts of the body. For example, on a scale from 0 to 1 with 0 being free passage of protein and 1 being impermeable to protein, the typical value for the reflection coefficient in most capillaries is >0.9. However, in the pulmonary capillaries the value is closer to 0.7 and approaches 0 in inflammatory states associated with increased capillary permeability.[6] As the value approaches 0, the capillaries are freely permeable not only to the usual fluid and electrolytes but to plasma proteins such as albumin. Because albumin accounts for approximately 80% of the plasma oncotic pressure, its free passage into the interstitial space effectively negates its intravascular oncotic benefit. 3 Although the Starling equation is useful to practitioners in terms of understanding the factors involved in fluid shifting between compartments, the rate and direction of transvascular flow cannot be calculated accurately in the clinical setting because most factors cannot be measured directly and the values for the factors vary in different capillaries in the body.

The body's compensatory mechanisms may have beneficial and harmful consequences. For example, cardiac output can be increased substantially by increases in stroke volume or heart rate. Although this may be useful for providing blood flow to inadequately perfused tissues, it may cause large increases in oxygen consumption by the heart that could aggravate preexisting ischemia in patients with underlying coronary artery disease (CAD). Another example is the sympathetic nervous system–mediated vasoconstriction that causes blood to shift from the skin, skeletal muscle, and some internal organs such as the kidneys and gastrointestinal tract to organs (e.g., heart and brain) that are less tolerant of inadequate flow. If the vasoconstriction continues unabated, the hypoperfused organs eventually become damaged. Figure 31–2 provides an overview of the compensatory changes that occur with a loss of circulating blood volume.

4 In addition to the more acute implications of hypovolemia and attendant complications, reperfusion damage is likely to occur, particularly after prolonged resuscitation attempts. In addition to edematous obstruction of capillaries and oxygen-free radical damage of cell membranes, a number of cellular (e.g., white blood cells and platelets) and humoral (e.g., procoagulants, anticoagulants, complement, and kinins) components are activated, causing the release of other inflammatory mediators.[6] The resulting reperfusion injury may range from readily reversible organ dysfunction to multiple-organ failure and death. The lungs are frequently the first system affected either by excessive fluid resuscitation or by the mediators of secondary reperfusion injury. The latter form of injury often results in the most severe form of acute lung injury known as the acute respiratory distress syndrome that is defined by an arterial oxygen tension: fraction of inspired oxygen ratio of less than 200 in the absence of hypervolemia.

Although the basic pathophysiology is similar for the various causes of hypovolemic shock, there are unique considerations relative to each. For example, whereas isolated head injuries associated with trauma typically do not result in substantial blood loss or shock, long bone or pelvic fractures may sequester several liters of blood. Patients with traumatic or thermal injuries, as well as postoperative patients, may have substantial fluid accumulation in sites where the fluid cannot be readily transferred back into blood vessels (i.e., third-spaced fluid) for maintaining pressure. With these types of injuries, prompt control of compressible bleeding sources with rapid patient transfer to the hospital for definitive treatment may preclude the cascade of events leading to shock. Indeed, with trauma patients, a "scoop and run" approach that places a priority on rapid transport to a hospital is used by most urban hospitals.

In the case of hemorrhagic shock, prompt attention must be given to cell as well as plasma losses. Red blood cells lost during the bleeding episode may lead to ischemic damage in vital organs. Packed red blood cell transfusions may be needed to increase the oxygen-carrying capacity of the blood because oxygen transport is a function not only of cardiac output but also of hemoglobin concentration and saturation and of hemoglobin affinity for oxygen. Once hemostasis has been achieved, a more restrictive transfusion strategy (i.e., transfusion if hemoglobin <7 g/dL) is indicated for the majority of patients without severe cardiovascular disease (see section on Trauma/Perioperative Patients).

Clotting factors and platelets are also lost in hemorrhage. The resulting bleeding problems may be aggravated by the dilutional effect of fluid resuscitation on clotting factor activity. Fresh-frozen plasma that contains necessary clotting factors and platelets are needed in massive blood loss to restore adequate coagulation. On the other hand, trauma patients are at increased risk for deep vein thrombosis and pulmonary embolism caused by multiple factors, including vessel damage, abnormal blood flow patterns, and the hypercoagulable state associated with injury. Therefore, some form of venous thromboembolism prophylaxis usually is indicated in multiple-trauma patients or patients with severe single-system injuries (e.g., spinal cord damage) once hemostasis of major injury-related bleeding has been achieved.

The pathophysiology becomes more complicated if the severity of shock is sufficient to require patient admission to the intensive care unit (ICU) after initial resuscitation or surgery. Most patients admitted to the ICU have SIRS, which is the body's response to injury. This syndrome is defined by a number of hypermetabolic changes reflected in the patient's temperature, white blood cell count and differential, and respiratory and heart rates. The stress response involves complex interactions between the nervous system and immunomodulating substances and has similar (if not the same) harmful and helpful consequences described with reperfusion following shock. If the underlying problems are left untreated, the patient with SIRS may develop multiple-organ dysfunction syndrome (MODS) during the final stages of illness.

CLINICAL PRESENTATION

5 The initial presentation of patients with suspected volume depletion can vary markedly, depending on factors such as age, concomitant disease states and medications, and the etiology and rapidity of depletion (see Clinical Presentation box). Intravascular depletion as a consequence of blood loss is signified by postural vital sign changes (i.e., changes in pulse and blood pressure between supine, sitting, and standing measurements), and such measurements should be performed unless the diagnosis is obvious, as in the case of bleeding associated with trauma. Early signs and symptoms of dehydration and intravascular depletion caused by gastrointestinal or urinary losses often are relatively nonspecific. Plasma volume losses of <10 mL/kg of body weight usually are associated with minor signs and symptoms of distress. Larger losses are not likely to be well tolerated (Table 31–2), particularly in patients older than 65 years. An 18-year-old athlete and a 65-year-old sedentary individual are likely to have much different responses to a similar amount of fluid loss. The young patient may lose one fourth of his or her circulating blood volume with minimal changes in arterial blood pressure and a relatively low heart rate. However, the elderly patient may have orthostatic changes in blood pressure that are not well tolerated by organs such as the kidneys.[4] Unfortunately, this same elderly patient may not have common signs and symptoms of volume depletion, such as skin turgor changes or thirst, but instead may have more subtle changes (e.g., mental status alterations).

CLINICAL PRESENTATION OF HYPOVOLEMIC SHOCK

General

- The initial presentation of adult patients with suspected volume depletion could vary markedly, depending on factors such as age, concomitant disease states and medications, and the etiology and rapidity of depletion.
- Plasma volume losses of <10 mL/kg of body weight usually are associated with minor signs and symptoms of distress.

Symptoms

- Patients may present with thirst, nausea, anxiousness, weakness, light-headedness, and dizziness.
- Patients may report scanty urine output and dark-yellow urine.

Signs

With more severe volume loss:

- Patients would have marked increases in heart rate (e.g., >120 beats/min) and respiratory rate (e.g., >30 breaths/min).
- Blood pressure would be decreased (e.g., systolic blood pressure <90 mm Hg).
- Mental status changes or unconsciousness may occur.
- Agitation may be present if the patient is conscious.
- Body temperature would be low or normal [e.g., 36°–37°C (96.8°–98.6°F)] in the absence of concomitant infection with cold extremities and decreased capillary refill on physical examination.

Laboratory Tests

- Sodium and chloride concentrations usually are high with acute depletion but may be low or normal depending on type of fluid intake.
- The ratio of blood urea nitrogen (BUN) to creatinine is likely to be elevated initially, but the creatinine level would increase as renal dysfunction occurs.
- Elevated base deficit and lactate concentrations in conjunction with decreased bicarbonate concentrations and pH due to metabolic acidosis.
- The complete blood count should be normal in the absence of concomitant disease states such as infection; in hemorrhagic shock, the red cell count, hemoglobin, and hematocrit would decrease over time, while the prothrombin time and international normalized ratio would increase.
- With more severe volume depletion, other organs may become dysfunctional, which may be reflected in laboratory testing (e.g., elevated transaminase levels with hepatic dysfunction).

Other Diagnostic Tests

- Urine output would be decreased to <0.5 to 1 mL/h.

The diagnosis of dehydration and intravascular depletion in children is complicated by difficulties in obtaining an accurate history. However, some excellent resources are available for healthcare providers, such as the Centers for Disease Control and Prevention (CDC) guidelines (*www.cdc.gov*), which discuss the evaluation and management of diarrhea in patients of all ages. In younger children, parental observations are important for estimating fluid deficits and deciding whether hospitalization is necessary. Fortunately, prospective data suggest that parental histories are predictive of acidosis and the need for hospitalization.[7] 6 Regardless of patient age or preexisting conditions, the initial monitoring of a patient with suspected volume depletion should include the following noninvasive parameters: vital signs, urine output, mental status, and physical examination (Fig. 31–3).

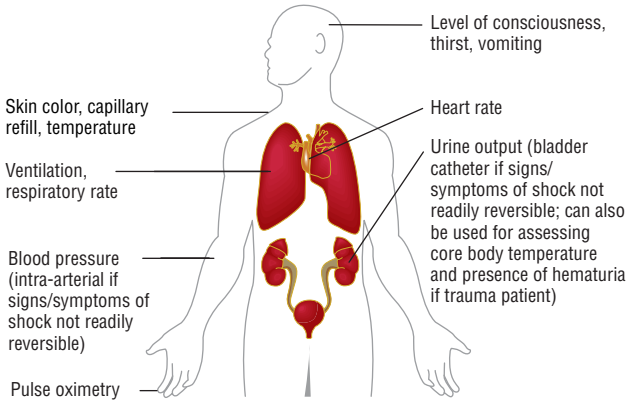

FIGURE 31-3. Noninvasive assessment of circulatory insufficiency.

TABLE 31-2 Acute Circulatory Insufficiency: Initial Presentation and Therapy[a]

	Mild	Severe
Plasma/blood loss	10 mL/kg adult 20 mL/kg child	30 mL/kg adult 35 mL/kg child
Mental status/level of consciousness	None–small changes (e.g., anxious, irritable)	Marked changes (e.g., confusion to unconsciousness)
Vital signs/orthostatic changes	Minor changes	Marked changes
Therapy	20 mL/kg lactated Ringer or normal saline IV[a] over 10–15 min Unlikely to need blood cell replacement even if hemorrhagic loss	Lactated Ringer or normal saline IV as rapidly as possible until response in adult, then decrease rate of infusion 20 mL/kg lactated Ringer or normal saline IV in child (repeat quickly if minimal response); likely to need blood cell replacement and surgery if hemorrhagic

[a]Patients may have intermediate degrees of volume loss in addition to those listed, but the amount of loss often is difficult to quantify. The presentations may also vary greatly in patients with similar amounts of loss (young athlete vs sedentary, elderly person). In patients particularly prone to complications associated with fluid overload, the fluid can be administered in multiple smaller boluses titrated to clinical response. See text for a more in-depth discussion of some of the guidelines in this table.

Although the presenting signs and symptoms of circulatory insufficiency are variable, patients usually have decreased blood pressure, increased heart and respiratory rates, and a normal or low–normal temperature (e.g., 36°–37°C [96.8°–98.6°F]) in the absence of infection, exposure to extremes of temperature, and medications that impair thermoregulation. As mentioned earlier, recordings of vital signs must be interpreted in light of known or suspected baseline conditions. For example, alcohol, β-blockers, butyrophenones such as haloperidol, diuretics, and medications with anticholinergic effects may impair thermoregulation.[8] Medications such as β-blockers and calcium channel blockers may alter resting blood pressure and heart rate, as well as the subsequent response to therapeutic interventions.

Although a blood pressure reading of 110/70 mm Hg (systolic/diastolic) may be acceptable in many patients, it may be inadequate in a patient with preexisting hypertension who normally has a blood pressure of 170/105 mm Hg. At the other extreme, patients with very low blood pressure may have inaudible or inaccurate determinations with cuff (sphygmomanometric) measurements. Chapter 19 details blood pressure measurement (e.g., cuff size, position). In this case, intraarterial monitoring is indicated. As a noninvasive tool, the respiratory rate may correlate better than the heart rate with volume loss, but respiratory rate often is not used.[4] The respiratory rate may be elevated because of anxiety or as a compensatory mechanism for the metabolic acidosis caused by lactic acidosis associated with poor tissue perfusion.

Although the kidneys continually produce urine, the bladder stores the urine for intermittent elimination. For the initial diagnosis and management of acute circulatory insufficiency, a catheter can be inserted into the bladder for measuring urine output. In contrast to thirst, which is a relatively insensitive indicator of volume depletion, urine output is generally diminished with inadequate fluid administration and increases with appropriate resuscitation. This presumes, of course, that acute renal failure or medications such as diuretics are not altering the expected response. Adults should produce at least 0.5 to 1 mL/kg/h of urine, whereas children up to 12 years of age should produce at least 1 mL/kg/h (2 mL/kg/h if younger than 1 year).

Mental status changes associated with volume depletion, if present, may range from subtle fluctuations in mood to unconsciousness. Although the latter finding typically is indicative of more severe depletion, less dramatic findings should not be interpreted as indicating mild fluid deficits. Losses of 4 L of plasma volume may be associated only with lassitude in an otherwise healthy adult patient.[4] Similar interpretation difficulties must be considered when performing the initial physical examination. An orderly progression

from warm, reddish skin with appropriate capillary refill (rapid return of blood flow to the extremity after removal of compression) to cold, cyanotic discoloration with impaired refill may not occur. Also, dry mucous membranes in elderly patients may be caused by mouth breathing or medications and not by fluid depletion.

TREATMENT

Hypovolemic Shock

DESIRED OUTCOME

The desired outcomes of therapy for patients with hypovolemic shock are to prevent further progression of the disease with subsequent organ damage and, to the extent possible, to reverse organ dysfunction that has already taken place.

GENERAL APPROACH TO TREATMENT

Milder forms of volume depletion may be managed in outpatient settings. For example, supplemental fluids can be added to the usual estimated daily requirements of 30 to 35 mL/kg in patients older than 12 years with dehydration. Commercially available carbohydrate/electrolyte drinks generally are more palatable than water and may promote earlier recovery. The rationale for combining carbohydrates with sodium is based on the cotransport absorption mechanism in the intestinal tract. With diarrheal states in particular, sodium absorption is impaired. Because water follows sodium, the diarrhea is likely to continue despite oral crystalloid fluid administration until the intestinal pathology resolves. However, when dextrose and sodium are combined in 1:1 equimolar amounts, both are absorbed via the cotransport mechanism, which also allows for absorption of water. This concept forms the basis for the World Health Organization's (WHO) oral rehydration solution, which contains 75 mmol/L of dextrose, 75 mmol/L of sodium, 20 mmol/L of potassium, 65 mmol/L of chloride, and 10 mmol/L of citrate for a total osmolarity of 245 mOsm/L.[3] Commercially available over-the-counter rehydration drinks for children in the United States also have an osmolarity of approximately 250 mOsm/L but typically contain 50 mmol/L or less of sodium, and the dextrose-to-sodium ratio often is 3:1. How these differences between commercially available formulations and the WHO rehydration formula might affect hospitalization rates is unclear, but ad hoc attempts to alter the commercially available products to make them more consistent with the WHO formula are not recommended.[3] Improper home mixing of a previous WHO formulation led to cases of hypernatremia.[9] Outpatient rehydration of children usually is recommended for those with uncomplicated (e.g., vomiting less than 48 hours) acute gastroenteritis and relatively mild dehydration after the exclusion of more severe illnesses such as bowel obstruction. 7 The need for intravenous (IV) rehydration often is overestimated. Randomized studies conducted in pediatric emergency departments have found oral rehydration to be at least as effective as IV rehydration.[10] In one study, children receiving oral rehydration for acute gastroenteritis had shorter lengths of stay than those receiving IV rehydration (225 vs 358 minutes; $P < 0.01$). Furthermore, there was a trend toward decreased hospital admissions in the oral compared with the IV rehydration group (11% vs 25%; $P = 0.2$).[11]

Hospitalization is indicated for more severe forms of circulatory insufficiency. If access to the circulatory system for administration of fluids and medication was not obtained prior to hospitalization, this should be a priority. Venous access generally is obtained during the preliminary examination process that includes the ABCs of life support (i.e., airway, breathing, and circulation), assessment of vital signs and mental status, and determination of urine output after catheterization. Whenever large-volume fluid resuscitation is expected, as in hemorrhagic shock, at least two IV catheters are desirable. Because flow is a function of tubing length and catheter diameter, large-bore peripheral IV lines are preferred over longer central lines. Unfortunately, vascular access in some patients may be problematic, and other routes (e.g., intraosseous infusion in children) may be necessary. One interesting method of fluid administration that has been investigated in elderly patients is subcutaneous infusion, or hypodermoclysis. With hypodermoclysis, common dextrose and sodium-containing fluids typically given by the intravenous route are given by subcutaneous infusion at sites such as the upper arm, chest, abdomen, or thigh, depending on factors such as patient or provider preference. Hyaluronidase has been used as a spreading agent to facilitate fluid absorption by this route, but its benefit versus risk profile has yet to be clearly elucidated; in particular, allergic reactions with this agent have been a concern, although a recombinant form is now available that has the potential for fewer reactions compared to the older bovine-derived products. Hypodermoclysis is not used commonly in the United States, probably because of concerns of adverse effects that were found in early studies that used excessively hypotonic or hypertonic solutions, as well as issues related to reimbursement when considered in ambulatory, home, or palliative care settings. Although relatively high fluid administration rates have been achieved in some studies involving hypodermoclysis, this method of infusion should not be used in patients with more severe forms of dehydration or hypovolemia until additional supportive information from clinical trials is available. Although alternative methods of fluid administration, such as hypodermoclysis, are desirable, well-conducted trials are needed before such methods can be recommended for routine use.

PHARMACOLOGIC THERAPY

8 Dextrose-in-water solutions may be appropriate for uncomplicated dehydration caused by water deprivation, but crystalloid (sodium-containing) solutions should be used for forms of circulatory insufficiency that are associated with hemodynamic instability. In the latter situation, IV solutions with sodium concentrations approximating normal serum sodium values usually are indicated because they cause more expansion of the intravascular and interstitial spaces compared with dextrose solutions (Table 31–3). Lactated Ringer's and normal saline solutions are examples of such crystalloid solutions that frequently need to be administered in large volumes when given to patients with more severe forms of hypovolemia (Table 31–4). A "large" amount of fluid does not mean a single bolus volume typically used as fluid challenge in a critically ill patient. An isolated bolus (e.g., 250–500 mL) in a young adult trauma patient is unlikely to cause a substantial change in blood pressure or acid–base balance.[12] Therefore, multiple fluid boluses usually are often needed in such patients to achieve hemodynamic stability in the perioperative period. On the other hand, overly aggressive fluid administration should be avoided, especially in patients with heart failure or impending pulmonary edema. In a randomized trial involving patients with acute lung injury and radiographic presence of pulmonary edema, a more conservative fluid management strategy led to significantly fewer ventilator-free days and days not spent in an ICU ($P < 0.001$).[13]

The choice between normal saline and lactated Ringer's solutions for hypovolemia is largely based on clinician preference. Traditionally, lactated Ringer's solution has been recommended for patients with hemorrhage because it is unlikely to cause the hyperchloremic metabolic acidosis that is seen with infusions of large volumes of normal saline. More recently, concerns have been raised relative to the proinflammatory effects (e.g., neutrophil

TABLE 31-3 Fluid Distribution and Major Indications[a]

Fluid	Intracellular	Interstitial	Intravascular	Major Indication
Normal saline or lactated Ringer	None	750 mL	250 mL	Intravascular repletion in symptomatic patients
3% sodium chloride	→	750 mL+	250 mL+	Small amounts (e.g., 250 mL) by intermittent infusion have been used in conjunction with normal saline or lactated Ringer for intravascular depletion in patients with head trauma
5% dextrose/0.45% sodium chloride	333 mL	500 mL	167 mL	Maintenance fluid in euvolemic or dehydrated (sodium and water loss) patients with mild signs/symptoms of volume depletion
5% dextrose	667 mL	250 mL	83 mL	Dehydration (primarily water loss) in patients with mild signs/symptoms of volume depletion
5% albumin	None	None	1,000 mL[b]	Intravascular repletion in symptomatic patients
25% albumin	→	→	1,000 mL+++[b]	Usually given by intermittent infusion of small volumes (e.g., 50–100 mL) or by continuous infusion titrated to response in hypovolemic patients with excess interstitial fluid accumulation

[a]Based on administration of 1 L of each solution *for comparative purposes only*. This amount of fluid, particularly for 3% saline and 25% albumin, would be inappropriate and likely harmful if given over a short period of time. Numbers are approximations; arrows indicate direction of fluid shift and plus signs indicate fluid pulled from other compartments.
[b]After distribution and attainment of steady-state conditions, 60% of albumin (and associated fluid) is in interstitial compartment and 40% is in intravascular compartment.

activation) of the L-isomer form of lactate that is contained along with the D-isomer in commercially available racemic isomer solutions. There are advocates for the use of lactated Ringer's solution containing only L-isomer lactate, particularly for more severe forms of hemorrhagic shock, since it avoids the proinflammatory effects of the racemic solution, while avoiding the hyperchloremia associated with normal saline.[14] Additionally, other substitutes for racemic lactate such as ketone or pyruvate have shown beneficial effects on neutrophil activation and gene expression in vitro and are the subject of ongoing studies.

Although lactated Ringer's solution does contain lactate, it does not cause substantial elevations in circulating lactate concentrations when used as a resuscitation solution.[15] Once adequate plasma volume has been restored by fluid administration, the body can readily clear the blood of the excess lactate that has accumulated from both anaerobic metabolism and from lactated Ringer's solution. However, blood samples for lactate determinations drawn through catheters (arterial and venous) that have not been cleared appropriately may have spurious increases or decreases in lactate concentrations because of retained lactated Ringer's and nonlactated solutions (e.g., varying concentrations of dextrose-in-water or sodium chloride), respectively.[16] Therefore, blood samples for lactate concentration determinations should be drawn from a catheter that has been cleared adequately (e.g., 5 mL) of infusate after temporarily stopping the fluid infusion.

A number of pharmacologic therapies show promise in animal models of shock, but few demonstrate success in subsequent trials involving patients with shock. In large part this is a result of the lack of acceptable animal models of shock that mimic the pathophysiology of patients.[17] In cases in which a relevant animal model is available, care must be taken when extrapolating the information to forms of shock other than the one under study. This may be the problem with naloxone, which has been shown to raise blood pressure in some studies of shock but not in others. While research continues on medications or fluids that improve oxygen transport, optimize oxygen utilization, reduce reactive oxygen species and reperfusion injuries, fluids remain the mainstay of therapy, although their use is not devoid of controversy.

TABLE 31-4 Adverse Effects of Plasma Expanders: Crystalloids

- Normal saline
  - Primarily extensions of pharmacologic actions (e.g., fluid overload, dilutional coagulopathy)
  - Hyperchloremic metabolic acidosis (has 154 mEq/L of chloride)
  - Hypernatremia (has 154 mEq/L of sodium)
- Lactated ringer
  - Primarily extensions of pharmacologic actions (e.g., fluid overload, dilutional coagulopathy)
  - Hyponatremia (has 130 mEq/L of sodium)
  - Aggravation of preexisting hyperkalemia (has 4 mEq/L of potassium)
- Hypertonic saline
  - Primarily extensions of pharmacologic actions (e.g., fluid overload, dilutional coagulopathy; intracellular volume depletion)
  - Hypernatremia (has 513 mEq/L of sodium)
  - Hyperchloremia (has 513 mEq/L of chloride)

Larger-molecular-weight solutions (i.e., >30,000) known as *colloids* have been recommended in conjunction with or as replacements for crystalloid solutions. Examples of colloids used as plasma expanders in the United States include albumin, hydroxyethyl starch, and dextran. Albumin is known as a *monodisperse colloid* because all its molecules are of the same molecular size and weight (~67,000), whereas hydroxyethyl starch and dextran solutions are *polydisperse compounds* with molecules of varying molecular size that are roughly proportional to molecular weight [weight *averaged* molecular weights of 600,000 (range 450,000–800,000) for 6% hetastarch in normal saline 450/0.75, 670,000 (range 450,000–800,000) for 6% hetastarch in lactated electrolyte 670/0.75, 130,000 (range 110,000–150,000) for 6% tetrastarch in normal saline 130/0.4, 40,000 (range 10,000–90,000) for dextran 40, or 70,000 to 75,000 (range 20,000–200,000) for dextran 70 or dextran 75, respectively]. In light of these differences, colloid comparisons are based on weight-averaged [(number of molecules at each weight × particle weight)/total weight of all molecules] or number-averaged (arithmetic mean of all particles' weights) molecular weight.[18] The size and weight differences of the colloids have important implications for the distribution of the products because lower-molecular-weight substances are retained in the intravascular space for a shorter period of time as a result of more rapid leakage across the vessel membrane. The theoretical benefit common to all colloids is based on their increased molecular weight (average molecular weight in the case of hydroxyethyl starch and dextran) that corresponds to increased intravascular retention time in the absence of increased capillary permeability compared with crystalloids. Even in patients with intact capillary permeability, the colloid molecules eventually will leak through the membrane. In the case of albumin with a distribution half-life of 15 hours in normal subjects, approximately 60% of administered albumin molecules (and associated fluid) would be shifted to the interstitial space within 3 to 5 days of exogenous administration. In patients with altered permeability (e.g., acute respiratory distress syndrome), the leakage of albumin from the intravascular to the

interstitial space may occur within hours, not days. The primary adverse effect concern of all colloids is fluid overload, which is an extension of their pharmacological action. Another adverse effect of increasing concern is renal dysfunction that seems to be related to hyperoncotic (e.g., 25%) albumin and other starch and dextran products. The mechanism of this adverse effect may be related to alteration of normal glomerular oncotic pressure differences or formation of lesions in the kidney.[19]

Albumin is available in 5% and 25% concentrations. Plasma protein fraction has oncotic actions similar to a 5% albumin solution, which is not surprising because albumin is the predominant protein in this product. When given in equipotent amounts, albumin is much more costly than crystalloid solutions. Additionally, the 5% and 25% albumin solutions typically are priced such that no cost-savings is associated with dilution of the 25% product to make a 5% concentration. In general, dilution should be avoided because of the possibility of preparation errors; cases of hemolysis and death have occurred when 25% albumin was inappropriately diluted with sterile water for injection, causing a dramatic lowering of effective osmolarity. The 5% albumin solution is relatively *isooncotic,* which means that it does not pull fluid into the compartment in which it is contained. In contrast, 25% albumin is referred to as *hyperoncotic* albumin because it tends to pull fluid into the compartment containing the albumin molecules. In general, the 5% albumin solution is used for hypovolemic states. The 25% solution should not be used for acute circulatory insufficiency unless it is used in combination with other fluids or it is being used in patients with excess total body water but intravascular depletion as a means of pulling fluid into the intravascular space. An example of the latter condition is cirrhosis with ascites in which total body water is substantially increased, but the patient is hypotensive as a consequence of lack of intravascular volume. To justify this use of hyperoncotic albumin from a cost-effectiveness standpoint presumes that there is evidence of adverse effects associated with the excess water (e.g., interstitial fluid accumulation in the lungs) and that the albumin remains in the intravascular space long enough to be of benefit. Albumin has a variety of functions beyond plasma expansion, such as binding properties, inflammatory gene modification, and antioxidant and free radical scavenging effects, which have been used to justify its administration instead of less expensive crystalloid or other colloid products. Although appealing theoretically, improved patient outcomes related to these properties have not been documented in adequately powered, randomized, controlled trials. Additionally, the clinician must realize that the properties of commercially available albumin products are not biologically identical to those of native albumin. For example, denaturation of the products may lead to inefficient binding and decreased oncotic activity.

Hydroxyethyl starch products have been developed as synthetic alternatives to albumin that is derived through the fractionation of donated human blood. The various products are differentiated by two numbers, one for the average mean molecular weight and one for the degree of hydroxyethyl substitution of glucose. For example, hetastarch is expressed as 450/0.7 based on weight and substitution, respectively. Most of the trials comparing albumin with hydroxyethyl starch products for volume expansion have found no significant differences in clinically important outcomes (e.g., mortality). Few trials have directly compared hydroxyethyl starch products with crystalloid solutions for intravascular expansion. Although hydroxyethyl starch products often are stated as being contraindicated in bleeding disorders, they have been most studied in patients with blood loss (e.g., trauma and perioperative patients). Hydroxyethyl starch should be avoided in situations where short-term impairments in hemostasis could have dire consequences, such as in patients undergoing cardiopulmonary bypass surgery and patients with intracranial bleeding. Hydroxyethyl starch may aggravate bleeding through mechanisms specific to this colloid (e.g., decreased factor VIII/von Willebrand factor). These mechanisms have not been well elucidated and often are difficult to distinguish from the dilutional effects on clotting factors caused by all plasma expanders; however, the risk of coagulopathy appears to be related to increasing starch substitution (greater than 0.4), and increasing doses and durations of administration.[20] Renal dysfunction associated with hydroxyethyl starch products may also be a function of starch substitution and high doses. In a study comparing a pentastarch (200/0.5) to a crystalloid solution for severe sepsis, the cumulative dose of the starch product was associated with an increased need for renal replacement therapy ($P < 0.001$) and a higher 90-day mortality ($P = 0.001$).[21] Hydroxyethyl starch may cause elevations in serum amylase concentrations but does not cause pancreatitis.

Dextran 40, dextran 70, and dextran 75 are available for use as plasma expanders in the United States. The numbers refer to the average molecular weight of the solutions. In general, dextran solutions are not used as often as albumin or hydroxyethyl starch products for plasma expansion, possibly because of concerns related to aggravation of bleeding (i.e., anticoagulant actions related to inhibiting stasis of microcirculation) and anaphylaxis that is more likely to occur with the higher-molecular-weight solutions. However, both of these concerns can be reduced if proper attention is paid to patient selection and, in the case of bleeding, published dosing guidelines with regard to the amounts of these products that should be infused. There are few comparative trials involving the dextran solutions, but the intravascular expansion within hours after infusion is approximately equal to the amount of dextran infused.

The crystalloid versus colloid debate was intensified when a meta-analysis by the well-respected Cochrane group found an overall increase in mortality associated with albumin using pooled results of randomized investigations.[22] The meta-analysis involved 30 randomized trials with 1,419 patients (relative risk of death with albumin vs no administration or crystalloid administration, 1.68; 95% confidence interval [CI], 1.26–2.23). For hypovolemia (caused by blood loss in the majority of studies), the risk of death associated with albumin administration was not quite statistically significant (relative risk, 1.46; 95% CI, 0.97–2.22). With the notable exception of trauma patients, a subsequent and more comprehensive systematic review did not find increased mortality attributable to albumin.[23] Furthermore, a landmark investigation involving almost 7,000 critically ill patients (conducted after the previously mentioned meta-analyses) did not find statistically significant differences in 28-day mortality between patients resuscitated with either normal saline or 4% albumin.[24] As in the previous meta-analysis, there was a trend toward increased mortality in patients with trauma, which became statistically significant ($P = 0.003$) when analyzed at 24 months in a subset of patients with traumatic brain injury.[25] This multicenter, randomized, double-blind investigation, referred to as the Saline versus Albumin Fluid Evaluation (SAFE) study, involved a heterogeneous group of ICU patients and was not sufficiently powered to look at various subsets, so clinicians must be cautious when extrapolating the results to more specific patient populations. With this caution in mind, this trial provides strong evidence that crystalloid solutions should be considered first-line therapy in patients with hypovolemic shock, particularly in the United States where cost differences between crystalloids and colloids are substantial.

SPECIAL POPULATIONS

Trauma/Perioperative Patients

The need for immediate treatment of hemorrhagic circulatory insufficiency with plasma expanders (i.e., crystalloids or colloids) seems obvious, but no large, well-controlled trials conducted in

humans have supported this practice. To the contrary, evidence suggests that fluid resuscitation beyond minimal levels (i.e., mean arterial pressure >40–60 mm Hg) is harmful in patients with penetrating abdominal trauma due to hemodilution and clot destabilization. One prospective study involving 598 adult patients with gunshot or stab wound injuries to the torso and systolic blood pressure measurements of 90 mm Hg or less found that delayed fluid resuscitation until operation was associated with increased survival and discharge from the hospital ($P = 0.04$).[26] Since concerns were expressed about the comparability of the immediate and delayed resuscitation groups, particularly because true randomization did not take place, a follow-up randomized trial was conducted to verify the findings. There were no differences in survival (four deaths in each group) in the second trial regardless of whether systolic blood pressure was titrated to >100 mm Hg or to 70 mm Hg.[27] Both studies were conducted in populated urban areas with approximately 2 hours from the time of injury to operation. Therefore, the results may not be applicable to rural areas with extended transport times. There also is a concern in applying the results of these investigations to patients with certain kinds of single-system injuries, particularly head trauma, where cerebral perfusion pressure is of primary importance. Although the applicability of these studies to other populations and settings is debatable, the *presumption* of benefits from immediate plasma expansion in all preoperative patients with circulatory insufficiency caused by hemorrhage is no longer valid. Instead, the initial priority should be surgical control of the bleeding source; until this is possible, fluids should be given in small aliquots to yield a palpable pulse and to maintain mean pressures no more than 60 mm Hg and systolic pressures no more than 90 mm Hg based on accurate measurements (e.g., arterial monitoring).

CLINICAL CONTROVERSY

Some clinicians believe that hypertonic solutions should be used to lower intracranial pressure in patients with head injuries.

By causing redistribution (i.e., pulling fluid) from the intracellular space, hypertonic solutions cause rapid expansion of the intravascular compartment, which is essential for vital organ perfusion. In head-injured patients, it has been postulated that this redistribution should decrease intracranial pressure because the vessels of the brain are more impermeable to sodium ions than are vessels in other areas of the body. Additionally, hypertonic saline solutions have beneficial immunomodulating actions when compared with more isotonic solutions in experiments with animals, although these actions have not always translated into similar beneficial effects in patients.[28]

Potential dosing and administration errors and related adverse events can occur when hypertonic saline is ordered and administered by clinicians relatively unfamiliar with its use. Potential adverse events include cellular crenation and damage caused by the dramatic fluid shifts associated with hypernatremia, hyperchloremic metabolic acidosis from hyperchloremia, and peripheral vein destruction from high osmolality. In the limited number of studies conducted in humans to date, such adverse effects have been uncommon and apparently of little clinical importance.[29,30]

Unfortunately, beneficial outcome data attributable to administration of these hypertonic solutions are lacking. Most of these studies were conducted in prehospital and emergency department settings using 250 mL of 7.5% sodium chloride with or without 6% dextran 70. A meta-analysis of randomized, controlled trials found no statistical difference between the survival rates of patients receiving the hypertonic saline solutions and those receiving standard isotonic crystalloid solutions.[31] Additionally, a subsequent double-blind, randomized controlled trial involving 229 patients with hypotension and severe brain injury demonstrated no significant differences in neurologic function at 6 months when 250 mL of 7.5% saline or lactated Ringer's solution was administered as part of a prehospital resuscitation regimen.[32] Part of the explanation for this finding may be related to supplemental crystalloid fluids that were given routinely to patients in both the treatment and control groups, which probably would increase the number of patients needed to demonstrate a statistically significant difference in mortality. It is interesting to note that the hypertonic saline solutions in such prehospital trials appear to have been administered by peripheral veins, despite their very high osmolality. This is deserving of further investigation since intravenous solutions with osmolality values above 600 to 1,200 mOsm/kg (the high end for some peripheral parenteral nutrition solutions) are usually administered through central catheters. For example, the osmolality of 3% sodium chloride is 1,026 mOsm/kg and it is typically recommended for central line administration.

In order to address ongoing questions of efficacy, the National Heart, Lung, and Blood Institute evaluated hypertonic saline for traumo patients with shock and severe traumatic brain injury. These two trials were conducted by a network of sites known as the Resuscitation Outcomes Consortium (ROC). The parallel trials were both stopped when it was determined that hypertonic saline was no better than normal saline and further enrollment would not change the 33 outcomes.[33] Therefore, normal saline is the fluid of choice when a hypertonic solution is desirable because it contains 154 mmol/L of both sodium and chloride. Given their relatively poor intravascular expansion and association with poor outcome in animal models of closed head injury, hypotonic solutions should be avoided in this population.[34]

In addition to crystalloid solutions, colloids have been used for plasma expansion in patients with perioperative circulatory insufficiency. In the United States, albumin and starch (i.e., hydroxyethyl starch) derivatives are used most commonly, although dextran solutions also are available commercially.

CLINICAL CONTROVERSY

Some clinicians believe that colloid solutions have advantages beyond crystalloid solutions that justify their use for patients with hypovolemic shock.

The major theoretical advantage of these compounds is their prolonged intravascular retention time compared with crystalloid solutions. In contrast to isotonic crystalloid solutions that have substantial interstitial distribution within minutes of IV administration, colloids remain in the intravascular space for hours or days, depending on factors such as capillary permeability.

The colloids, particularly albumin, are expensive solutions. Therefore, it is difficult to justify the additional cost of colloidal products unless the benefit-to-risk ratio is substantially greater than that associated with inexpensive crystalloid solutions. This does not appear to be the case based on randomized, controlled studies and meta-analyses comparing colloid and crystalloid solutions for acute circulatory insufficiency. Because other colloids, such as hydroxyethyl starch, almost always have been compared with albumin and not with crystalloid solutions in published clinical studies (with no clinically important differences found), there is no reason to suspect that these other colloids have any unique advantages as volume expanders. Adverse effects associated with colloids appear to be

TABLE 31-5 Adverse Effects of Plasma Expanders: Colloids

- Albumin
  - Primarily extensions of pharmacologic actions (e.g., fluid overload; dilutional coagulopathy)
  - Amino acid profile and catabolism alterations (clinical significance?); potential protein overload if given with exogenous protein (e.g., parenteral nutrition)
  - Anaphylactoid/anaphylaxis reactions (life-threatening reactions rare; higher in patients with immunoglobulin A deficiency)
  - Infectious complications (all reported cases have been associated with improper handling by manufacturer or institution; no reported cases of human immunodeficiency virus or hepatitis transmission)
  - Interactions with medications and nutrients (clinical significance varies)
  - Metal loading, particularly aluminum (long-term administration in patients with renal failure)
  - Negative inotropic effect; reductions in ionized calcium concentrations (not well documented)
  - Pyrogenic reactions (not well documented)
  - Renal dysfunction with hyperoncotic albumin
- Hydroxyethylstarch
  - Primarily extensions of pharmacologic actions (e.g., fluid overload, dilutional coagulopathy)
  - Bleeding (decreases factor VIII/C activity; not recommended in patients at high risk for bleeding or in patients with severe bleeding conditions such as subarachnoid hemorrhage)
  - Macroamylase formation may cause elevation in blood amylase that leads to inaccurate diagnosis of pancreatitis
  - Anaphylactoid/anaphylaxis reactions
  - Pruritus (particularly when large amounts are given; may take months to resolve)
  - Renal dysfunction
- Dextrans
  - Primarily extensions of pharmacologic actions (e.g., fluid overload, dilutional coagulopathy)
  - Anaphylactoid/anaphylaxis reactions (increased incidence of anaphylaxis with increased molecular weight)
  - Bleeding (sometimes used for anticoagulant activity, so not recommended for patients with severe bleeding)
  - Renal dysfunction

TABLE 31-6 General Indications for Blood Products in Acute Circulatory Insufficiency Due to Hemorrhage[a]

- Packed red blood cells
  - Increase oxygen-carrying capacity of blood: Usually indicated in patients with continued deterioration after volume replacement or obvious exsanguination; must be warmed, particularly when used in children
- Fresh-frozen plasma
  - Replacement of clotting factors: Generally overused; indicated if ongoing hemorrhage in patients with PT/PTT >1.5 times normal, severe hepatic disease, or other bleeding diathesis
- Platelets
- Used for bleeding due to severe thrombocytopenia (i.e., platelet count <10,000 mcL) or rapidly dropping platelet counts as would occur with massive bleeding
- Other products
  - With the exception of recombinant activated factor VII, which is currently undergoing trials for use in life-threatening hemorrhage unresponsive to traditional blood product administration, components such as cryoprecipitate and factor VIII are generally not indicated in acute hemorrhage but rather are used after specific deficiencies are identified

[a]Although whole blood can be used for large-volume blood loss, most hospitals use component therapy, and use crystalloids or colloids for plasma expansion. PT, prothrombin time; PTT, partial thromboplastin time.

uncommon and generally are extensions of their pharmacologic activity (Table 31–5), but this is also true of crystalloids. The benefit-to-risk ratio appears to be similar for colloids and crystalloids; thus, based on cost, crystalloids are preferred for initial treatment of circulatory insufficiency in patients with hemorrhagic shock.

The preceding discussion dealt primarily with acute circulatory insufficiency, but there are other considerations with regard to fluid replacement in elective surgical procedures. Preoperative fluid deficits in patients undergoing minor procedures may be associated with increased perioperative morbidity, some of which (e.g., drowsiness, dizziness) may be reduced by appropriate fluid administration prior to surgery.[35] However, care must be taken to avoid overhydration in the perioperative period because excess fluid will lead to weight gain and decreased pulmonary function. Some evidence suggests that fluid restriction on the day of surgery may reduce postoperative morbidity in patients undergoing major surgical procedures. In one randomized, multicenter trial, use of a restricted intraoperative and postoperative IV fluid protocol led to significantly fewer cardiopulmonary (7% vs 24%; $P = 0.007$) and wound (16% vs 31%; $P = 0.04$) complications.[36] As the preceding discussion indicates, the benefits and risks of fluid administration in the perioperative period are not just a function of too little or too much fluid but involve other patient- and procedure-related issues.

Another consideration in the patient with penetrating injuries or surgery is the potential need for blood product administration (Table 31–6) to replace oxygen-carrying and clotting functions. Although a small group of trauma patients respond to the initial fluid bolus and remain stable, most patients respond initially and then deteriorate. The latter patients, as well as patients undergoing blood loss associated with surgery, frequently need blood components such as packed red blood cells. 9 In the case of the latter component, red blood cells contain hemoglobin that delivers oxygen to tissues. Neither crystalloids nor colloids perform this function.

Administration of excessive blood products may be counterproductive. In the case of red blood cells, attempts to raise the hematocrit to high–normal or supranormal concentrations may decrease oxygen delivery by increasing blood viscosity. Additionally, there are immunomodulatory concerns with red blood cell administration. Although there is no optimal hematocrit value for all patients, a minimum hematocrit concentration of 30% (equivalent to a hemoglobin concentration of 10 gm/dL) traditionally has been used as the threshold for transfusion, particularly in patients at risk for ischemia, such as those with CAD. Use of a more liberal transfusion strategy has been curtailed in many institutions with the publication of a randomized, multicenter trial involving critically ill patients that found 30-day mortality to be similar whether patients were transfused at a hemoglobin concentration less than 7 or 10 g/dL (18.7% vs 23.3%, respectively; $P = 0.11$).[37] The mortality during hospitalization was significantly lower in the restrictive group (22.2% vs 28.1%; $P = 0.05$). Although the investigators were cautious about extrapolating the results of this investigation to patients with myocardial ischemia, the study does question the use of a liberal transfusion strategy for critically ill patients.

Blood products have risks beyond immunomodulation. There is the rare but important risk of virus transmission [e.g., human immunodeficiency virus (HIV), hepatitis]. Citrate that is added to stored blood to prevent coagulation may bind to calcium, resulting in hypocalcemia, although potassium and phosphate concentrations often are elevated in stored blood, particularly when hemolysis has occurred during storage. In patients receiving large amounts of blood, prophylactic calcium administration may be warranted until levels are available. Other issues that must be considered with blood product administration include monitoring for transfusion-related reactions and attention to appropriate warming, particularly when large volumes are given to pediatric patients, because hypothermia is associated with increased fluid requirements and mortality.

Since its commercial release in the United States, recombinant factor VIIa has been used for a variety of off-label uses related to trauma and bleeding. For example, in patients with massive blood loss a cocktail of cryoprecipitate, platelets, and recombinant factor

VIIa has been suggested to rapidly attain hemostasis.[38] These more severe forms of blood loss are not only a function of the type of injury but also factors such as medications (e.g., aspirin, coumadin, clopidogrel, enoxaparin) and disease states that impair normal coagulation. Large well-controlled trials are needed to define the role of recombinant factor VIIa in clinical practice given its high cost and potential thromboembolic complications. There are specific concerns with its use in trauma patients related to subpopulations most likely to see benefit since there are issues related to appropriate dose, timing, and diminished effectiveness in patients with acidosis and severe hypothermia. A large randomized controlled trial involving patients with penetrating and blunt trauma is currently underway that should help to resolve many of these concerns.[39]

The periodic shortages, high costs, and adverse effect concerns related to blood products have prompted investigations of alternative "bloodless" strategies. In addition to the use of more restrictive transfusion thresholds, as mentioned previously, these strategies have included hemoglobin-based oxygen carriers and perfluorocarbon compounds to deliver oxygen to tissues. Other strategies have aimed at reducing blood loss through the use of improved procedural and surgical techniques, as well as the administration of hemostatic medications.

Patients with Thermal Injuries

There are a number of formulas for estimating fluid requirements in thermally injured patients, but there is little reason to choose one over another based on well-controlled studies. In general, the amount of loss corresponds to the size of the thermal injury. Guidelines recommend approximately 2 to 4 mL/kg of isotonic fluid (lactated Ringer's solution) for each percent burn can be used for calculating the expected fluid requirements for the first 24 hours after the burn.[40] For example, a 60-kg person with 30% body surface area (BSA) burns is expected to require 5,400 to 7,200 mL of fluid over the initial 24 hours. Regardless of the calculated deficit, fluids should be administered until adequate tissue perfusion has been documented (e.g., maintenance of urine output of 0.5–1 mL/kg in adults) or adverse effects (e.g., pulmonary edema) occur. Crystalloids are preferred as initial therapy for burn victims because there is no substantial evidence that colloids mobilize edematous fluid, and there is a theoretical concern that extravascular fluid accumulation might be prolonged by the oncotic actions of albumin and other colloid products that have leaked through vessel walls.[41] Additionally, there is no evidence that colloids reduce mortality in patients with thermal injuries. Some novel therapies for thermal resuscitation have been studied, although larger confirmatory trials are needed prior to use apart from research protocols. For example, in a prospective study involving patients with >30% BSA burns, antioxidant therapy with extremely high doses on IV vitamin C (66 mg/kg/h for 24 hours) reduced resuscitation fluid requirements and wound edema.[42] The proposed mechanism is reduction in free radical–induced increases in capillary permeability.

CLINICAL CONTROVERSY

The appropriate use of invasive hemodynamic monitoring tools, such as right-sided heart catheterization in patients with hypovolemic shock, is controversial.

ONGOING MONITORING

One form of monitoring that may take place in the emergency and operating rooms, as well as in the ICU, requires placement of a central venous pressure (CVP) line. Monitoring of CVP provides the clinician with a somewhat insensitive yet useful estimate of the relationship between increased right atrial pressure and cardiac output. A protocol that used a particular type of central catheter to perform continuous monitoring of central venous oxygen saturation in conjunction with so-called goal-directed therapy in the first 6 hours of patient arrival in an urban emergency department resulted in decreased mortality compared with standard monitoring (30.5% vs 46.5%; $P = 0.009$).[43] However, the patients in this study had severe sepsis and septic shock, so the results might not be applicable to other forms of shock with different pathophysiologic considerations. For example, in hemorrhagic shock due to trauma, the most important intervention is surgical control of bleeding, and anything that delays this control is likely to increase, not decrease, mortality. Until additional studies have been performed, it would be premature to mandate goal-directed therapy with the associated central venous monitoring in patients with nonseptic forms of shock, particularly shock due to blood loss. In fact, so-called "upstream" measurements of perfusion such as CVP are not a useful guide for fluid management in hospitalized patients,[44] and are being replaced by "downstream" markers such as urine output and lactate levels that are more likely to reflect end-organ dysfunction.[45] A more complete discussion of invasive and noninvasive hemodynamic monitoring is given in Chapter 30.

A number of laboratory tests are indicated for subacute monitoring of shock in the ICU setting. These include a renal battery for assessing possible electrolyte alterations and kidney perfusion (e.g., BUN and creatinine). Among other things, a complete blood count will enable assessment of possible infection (white blood cell count), oxygen-carrying capacity of the blood (hemoglobin, hematocrit), and ongoing bleeding (hemoglobin, hematocrit, and platelet count). The prothrombin time or international normalized ratio and partial thromboplastin time will give an indication of the ability of the blood to clot because, in the case of hemorrhagic shock, clotting factors are lost and diluted. An increasing lactate concentration (arterial, mixed venous, or central venous), an increasing arterial base deficit, or a decreasing bicarbonate concentration are global markers indicative of inadequate perfusion leading to anaerobic metabolism with accumulation of lactic acid. Although the value of these surrogate markers for improving patient outcomes is more controversial, they are considered traditional end points of resuscitation in certain populations such as trauma patients.[46] Other tests may be indicated if organ dysfunction is likely. For example, when blood flow to the liver is interrupted because of sustained hypotension, a condition known as *shock liver* may occur. In this condition, the levels of transaminases on a liver panel may be markedly elevated in the first couple of days after marked hypotension, although the concentrations should decrease over time.[4] Along with laboratory testing, a more extensive history can be obtained during the subacute monitoring period.

The value of pulmonary artery catheters (also known as right-sided heart or Swan-Ganz catheters) has been debated hotly since their introduction. Such catheters are placed to obtain various oxygen-transport variables, some of which cannot be determined reliably from peripheral or other central vessels. The debate was intensified when early studies suggested improved outcomes when cardiac output and other oxygen-transport variables were raised to supranormal levels, the monitoring of which required placement of a pulmonary artery catheter. Subsequent studies using similar monitoring parameters associated with pulmonary artery catheterization gave conflicting results.[47]

The controversy led to consensus conferences and workshops, the development of organizational guidelines, and the publication of a meta-analysis (which found a statistically significant reduction in *morbidity* using pulmonary artery catheters to guide therapy).[48] Ultimately, a large randomized, controlled trial involving pulmonary artery catheters was conducted in high-risk surgical patients.[49]

The trial involved 1,994 patients. The mortality was almost identical for the catheter and control groups (7.8% vs 7.7%; 95% CI, 2.3–2.5). There were no episodes of pulmonary embolism in the catheter group and eight episodes in the control group ($P = 0.004$). This trial is important not only because of the implications for high-risk surgical patients but also because it allows for the conduct of future trials in other patient populations without some of the ethical issues raised about such trials in the past.

Part of the concern regarding pulmonary artery catheterization relates to interpretation of its results by inexperienced practitioners. Studies in Europe and the United States found that one of two physicians incorrectly interpreted a tracing from a pulmonary artery catheter.[50] This could explain some of the results of studies finding no benefits to pulmonary artery catheterization or, in some cases, worse outcomes in the pulmonary artery catheterization group by actions taken as a result of inaccurate measurements or misinterpretation of information obtained from the monitoring process.

Complications related to pulmonary artery catheter insertion, maintenance, and removal include damage to vessels and organs during insertion, arrhythmias, infections, and thromboembolic damage. To avoid the complications associated with pulmonary artery catheterization, other less invasive tools were developed to obtain similar information. For example, cardiac output determinations have been made by Doppler, bioimpedance, dye, and ionic dilution techniques, although such measurements would not provide other data that are obtained routinely with pulmonary artery catheters (e.g., left-sided heart filling pressure). Additionally, advances in pulmonary artery catheter technology that expand the information obtained from such monitoring (e.g., mixed venous oxyhemoglobin) are under investigation. However, given the lack of well-defined outcome data associated with pulmonary artery catheterization, its use is best reserved for complicated cases of shock not responding to conventional fluid and medication therapies.

Commonly measured and calculated hemodynamic and oxygen-transport indices associated with invasive monitoring are primarily global indicators of tissue perfusion. Attempts have been made to find regional and local indicators of hypoperfusion so that circulatory insufficiency could be treated before overt shock occurs. One focus of recent research has been monitoring modalities involving the gastrointestinal tract.

Although the literature is fairly consistent concerning low gastric intramucosal pH (pHi) values being predictive of death, pHi-guided therapy to decrease mortality has not been demonstrated.[51] Additionally, a number of technical considerations remain to be resolved when using pHi or, more recently, capnometry (luminal P_{CO_2} tonometry) for monitoring and therapy. Despite these concerns, measures of regional tissue oxygenation continue to be investigated through a variety of novel monitoring techniques.

In addition to regional monitoring of tissue perfusion, local methods of monitoring are being studied. For example, subcutaneous measurement of tissue oxygen pressure shows promise in preliminary investigations. Regional and local measurements likely will not replace more global indicators of perfusion; rather, the methods will complement each other.

ONGOING MANAGEMENT

Proper attention to plasma expansion must be continued into the intraoperative and postoperative periods. A number of neurohormonal changes take place that affect urine output, and patients may have substantial third spacing of fluid depending on the operation and preexisting conditions. Furthermore, postoperative patients are prone to hyponatremia from renal generation of electrolyte-free water and from antidiuretic hormone release.[52] As in acute resuscitation, the administration of hypotonic solutions in the perioperative period does not prevent the decrease in extracellular volume that often occurs. Therefore, although excess fluid administration is to be avoided in the perioperative setting, isotonic crystalloid solutions should be used when fluids are indicated to prevent intravascular depletion and circulatory insufficiency. There is general agreement that the choice of crystalloid solution in the perioperative period should be either normal saline or a lactated Ringer's (or equivalent) solution. However, there is substantial debate as to which of these two solutions is preferable since comparative studies have involved small numbers of patients.[53]

Of the randomized studies comparing albumin with crystalloid solutions in the perioperative period, the majority found no statistically significant differences between groups.[54] Any significant differences found involved isolated hemodynamic or respiratory variables with no obvious clinical correlates (e.g., duration of mechanical ventilation). Therefore, albumin and other colloids cannot be recommended for the prevention or initial treatment of circulatory insufficiency, although their use may be appropriate in patients who are not responding to crystalloids and are developing problems such as interstitial fluid accumulation. Practice guidelines published by a consortium of academic medical centers reflect this recommendation, but colloids continue to be used widely.[55]

In contrast to many other forms of shock, medications are not indicated in the initial therapy of hypovolemic shock but rather play an adjunctive role in patients who continue to have circulatory insufficiency after fluids have been maximized and volume overload concerns exist.[56] In a multicenter cohort study of blunt-injured patients with hemorrhagic shock, the use of vasopressors within 12 hours of injury was associated with significantly higher mortality at 24 hours ($P = 0.001$).[57] With hypovolemia, the body's natural response is to increase cardiac output and to constrict blood vessels to maintain blood pressure. There is no evidence that vasoactive medications improve outcome in patients with hypovolemic shock assuming that fluid therapy is adequate. 10 However, once the cause of acute circulatory insufficiency has been stopped or treated and fluids have been optimized, some patients continue to have signs and symptoms of inadequate tissue perfusion. This may be caused by reperfusion injury. Although the search for a cryptogenic source (e.g., intraabdominal bleeding in a trauma patient) should continue, the clinician may need to administer vasoactive medications to improve perfusion.

Pressor agents such as norepinephrine and high-dose dopamine are to be avoided, if possible, because they may increase blood pressure at the expense of peripheral tissue ischemia. Some sources use stronger language and state that vasopressors are contraindicated in certain forms of shock (e.g., hemorrhagic). This does not help the clinician who is treating a patient with unstable blood pressure despite massive fluid replacement and increasing interstitial fluid accumulation. In such situations, inotropic agents such as dobutamine are preferred if blood pressure is adequate (e.g., systolic blood pressure ≥80–90 mm Hg) because they should not aggravate the existing vasoconstriction. The inotropic agents are justified by presumed inadequate cardiac output for the specific situation, although the measured values may be in the normal range.

When pressure cannot be maintained with inotropic agents or when inotropic agents with vasodilatory properties cannot be used because of inadequate blood pressure concerns, pressors may be required as a last resort. In general, the need for pressors is predictive of the development of MODS and increased length of hospital stay.[58] Although the response to pressor agents may be variable in hypovolemic shock, there does not appear to be resistance as a consequence of altered receptor response, as is sometimes seen in patients with septic shock.[4] Potent vasoconstrictors such as norepinephrine and phenylephrine should be given through central veins because of the possibility of extravasation and necrosis with peripheral administration.

In managing patients with hypovolemic shock, the clinician must be aware of potential adverse effects of medications being used for supportive care purposes. For example, some patients are particularly susceptible to the histamine release associated with morphine and may have substantial decreases in blood pressure. Sodium bicarbonate would seem to be a logical therapy in patients with shock who typically have a metabolic acidosis, but bicarbonate administration has not been shown to improve surrogate hemodynamic markers or patient outcomes and has known disadvantages such as the associated increase in arterial carbon dioxide levels and decrease in serum ionized calcium levels.[59] Propofol is commonly used for sedation in the ICU, but it may cause substantial decreases in blood pressure. The initial dose of propofol probably should be decreased by at least 50% in patients with hemorrhagic shock who have recently been resuscitated and by at least 80% (if it is given at all) in patients who may not be fully resuscitated.[60]

A number of interesting treatments for shock are under investigation, including autotransfusion for removing harmful cytokines from the body. Various alternatives to conventional blood components also are being studied, such as stroma-free hemoglobin and perfluorocarbon compounds, as virus-free alternatives to red blood cell transfusion. Hopefully, these methods will be useful adjuncts to adequate volume replacement, which is the primary therapeutic intervention in managing acute circulatory insufficiency as a result of volume depletion.

PHARMACOECONOMIC CONSIDERATIONS

The primary therapy for hypovolemic shock is fluid replacement. The institutional cost of 1 L of most crystalloid solutions is less than $1. Assuming that such fluids are used, the associated costs of personnel and equipment then become the primary economic considerations in the resuscitation of patients with hypovolemic shock. However, as mentioned, many clinicians recommend that colloid plasma expanders (e.g., albumin, hydroxyethyl starch, or dextrans) be used to replace some or all of the standard crystalloid solutions. Although the costs of these solutions vary, depending on contractual arrangements, as might occur with purchasing groups, in general, albumin solutions are more expensive than hydroxyethyl starch and dextran products. All these solutions are markedly more costly than crystalloid solutions; in some cases, the differences are 50- to 100-fold, even when used in equipotent amounts.

The only trial that investigated albumin use on a large-scale basis was an observational study involving 15 academic medical centers in the United States. Based on previously published guidelines, 62%

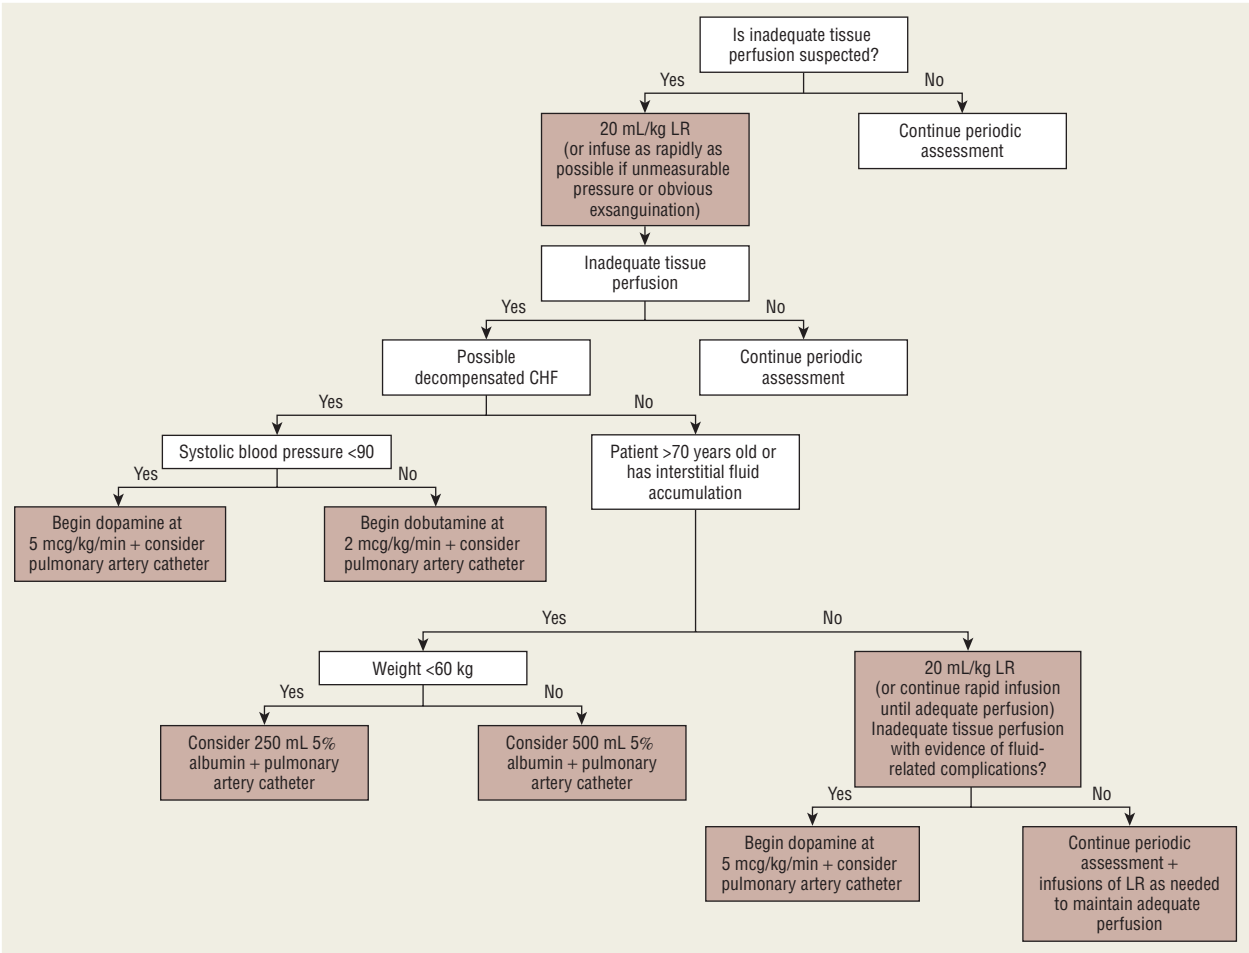

FIGURE 31-4. Hypovolemia protocol for adults. This protocol is not intended to replace or delay therapies such as surgical intervention or blood products for restoring oxygen-carrying capacity or hemostasis. If available, some measurements can be used in addition to those listed in the algorithm, such as mean arterial pressure or pulmonary artery catheter recordings. The latter can be used to assist in medication choices (e.g., agents with primary pressor effects may be desirable in patients with normal cardiac outputs, whereas dopamine or dobutamine may be indicated in patients with suboptimal cardiac outputs). Lower maximal doses of the medications in this algorithm should be considered when pulmonary artery catheterization is not available. Colloids that can be substituted for albumin are hydroxyethyl starch 6% and dextran 40. See text for an in-depth discussion of these and other issues involved in this protocol. (CHF, congestive heart failure; LR, lactated Ringer's solution.)

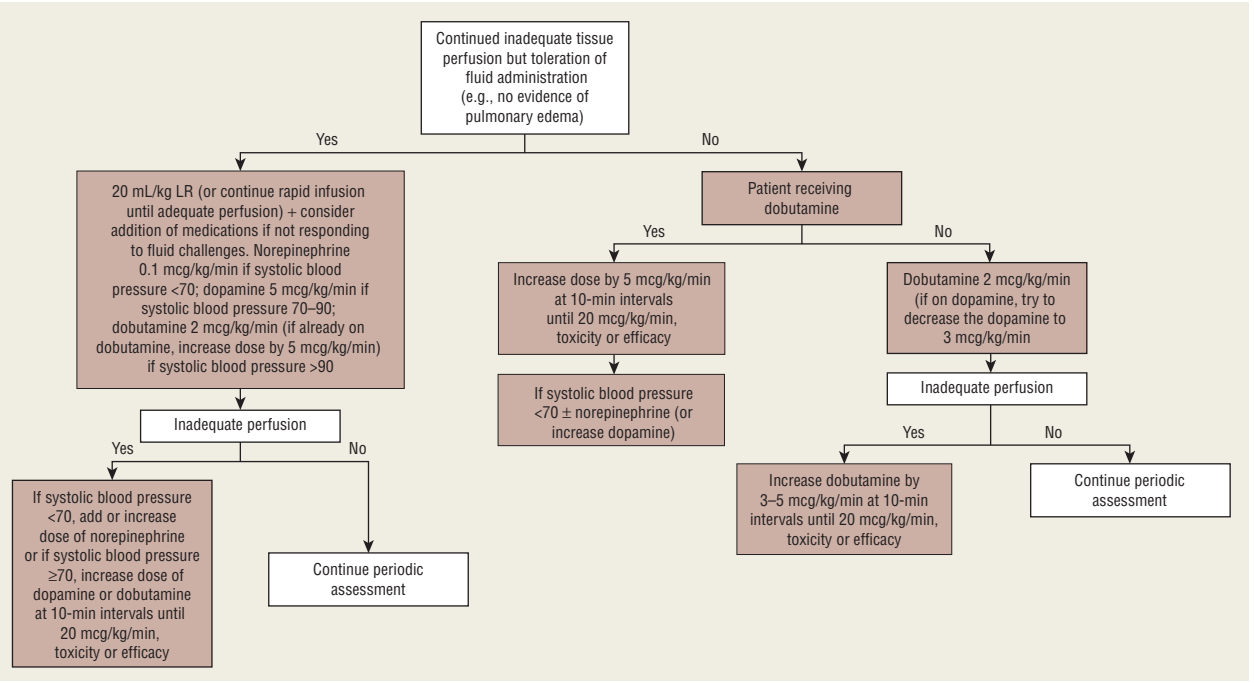

FIGURE 31-5. Ongoing management of inadequate tissue perfusion. (LR, lactated Ringer's solution.)

of albumin use was defined as inappropriate, at a cost of $124,939.[61] Presuming equal efficacy and toxicity (as available studies indicate) between crystalloid and colloid solutions, cost-minimization analysis clearly indicates the economic advantages of the crystalloids.

Because medications are not simply alternatives to crystalloids but rather are used when crystalloid therapy has been optimized, there is little reason to compare medication and fluid therapies from an economic perspective. Furthermore, there are no economic comparisons of the various inotropic and vasopressor medications used in the treatment of hypovolemic shock.

EVALUATION OF THERAPEUTIC OUTCOMES

Figure 31–4 is an algorithm that summarizes many of the treatment principles discussed in this chapter. The algorithm is an example of one approach to the adult patient presenting with hypovolemic shock. It presumes that initial rehydration attempts (i.e., outpatient or prehospital) were unsuccessful in restoring circulation. Obviously, modifications may be needed for patient-specific forms of hypovolemic shock. Other limitations of the algorithm should be recognized, particularly the decisions to add or to substitute colloid or medication therapies when crystalloid solutions are not yielding desired results and when to perform pulmonary artery catheterization for more invasive monitoring. Medications become more important for the ongoing management of hypovolemic shock, particularly when the patient is unresponsive to fluids (Fig. 31–5). Medications for more complicated cases of hemorrhagic shock should not detract from the primary effective resuscitative measure—surgical stabilization of bleeding.

SECTION 3
RESPIRATORY DISORDERS

CHAPTER 32

Introduction to Pulmonary Function Testing

JAY I. PETERS AND STEPHANIE M. LEVINE

KEY CONCEPTS

1. Normal ventilation–perfusion ratio. The function of the lungs is to maintain Pa_{O_2} and Pa_{CO_2} within normal ranges. This goal is accomplished by matching 1 mL mixed venous blood with 1 mL fresh air ($\dot{V}/\dot{Q} = 1$). Normally, ventilation ($\dot{V}$) is less than perfusion ($\dot{Q}$), and $\dot{V}/\dot{Q}$ ratio is 0.8.
2. The air in the lung is divided into four compartments: tidal volume—air exhaled during quiet breathing; inspiratory reserve volume—maximal air inhaled above tidal volume; expiratory reserve volume—maximum air exhaled below tidal volume; and residual volume—air remaining in the lung after maximal exhalation. The sum of all four components is the total lung capacity.
3. Obstructive lung disease is defined as an inability to get air out of the lung. It is identified on spirometry when FEV_1/FVC (force expiratory volume in the first second of expiration/forced vital capacity [total amount of air that can be exhaled during a forced exhalation]) is <70% to 75%.
4. Reversible airway obstruction is common in asthma and chronic obstructive pulmonary disease. An increase in FEV_1 of 12% (and >0.2 L in adults) after an inhaled β-agonist suggests an acute bronchodilator response.
5. Restrictive lung disease is defined as an inability to get air into the lung and is best defined as a reduction in total lung capacity. It is suspected when FVC is low and FEV_1/FVC is normal.
6. Restrictive lung disease can be produced by a number of defects, such as increased elastic recoil (interstitial lung disease), respiratory muscle weakness (myasthenia gravis), mechanical restrictions (pleural effusion or kyphoscoliosis), and poor effort.

The primary function of the respiratory system is to maintain normality of arterial blood gases, that is, arterial pressure of oxygen (Pa_{O_2}) and arterial pressure of carbon dioxide (Pa_{CO_2}). To achieve this goal, several processes must be accomplished, including alveolar ventilation, pulmonary perfusion, ventilation—perfusion matching, and gas transfer across the alveolar—capillary membrane. Alveolar ventilation is achieved by the cyclic process of air movement in and out of the lung. During inspiration, the inspiratory muscle contracts and generates negative pressure in the pleural space. This pressure gradient between the mouth and the alveoli draws fresh air (tidal volume) into the lung. Approximately one third of the inspired gas stays in the conducting airways (dead space), and two thirds reaches the alveoli.

CHAPTER 33

Asthma

H. WILLIAM KELLY AND CHRISTINE A. SORKNESS

KEY CONCEPTS

1. Asthma is a disease of increasing prevalence that is a result of genetic predisposition and environmental interactions; it is one of the most common chronic diseases of childhood.
2. Asthma is primarily a chronic inflammatory disease of the airways of the lung for which there is no known cure or primary prevention; the immunohistopathologic features include cell infiltration by neutrophils, eosinophils, T-helper type 2 lymphocytes, mast cells, and epithelial cells.
3. Asthma is characterized by either the intermittent or persistent presence of highly variable degrees of airflow obstruction from airway wall inflammation and bronchial smooth muscle constriction; in some patients, persistent changes in airway structure occur.
4. The inflammatory process in asthma is treated most effectively with corticosteroids, with the inhaled corticosteroids having the greatest efficacy and safety profile for long-term management.
5. Bronchial smooth muscle constriction is prevented or treated most effectively with inhaled β_2-adrenergic receptor agonists.
6. Variability in response to medications requires individualization of therapy within existing evidence-based guidelines for management. This is most evident in patients with severe asthma phenotypes.
7. Ongoing patient education, for a partnership in asthma care, is essential for optimal patient outcomes and includes trigger avoidance and self-management techniques.

Asthma has been known since antiquity, yet it is a disease that still defies precise definition. The word *asthma* is of Greek origin and means "panting." More than 2,000 years ago, Hippocrates used the word *asthma* to describe episodic shortness of breath; however, the first detailed clinical description of the asthmatic patient was made by Aretaeus in the second century.[1] The National Institutes of Health, National Asthma Education and Prevention Program Expert Panel Report 3 (EPR3), has provided the following working definition of asthma:[2]

> Asthma is a chronic inflammatory disorder of the airways in which many cells and cellular elements play a role: in particular, mast cells, eosinophils, T-lymphocytes, macrophages, neutrophils, and epithelial cells. In susceptible individuals, this inflammation causes recurrent episodes of wheezing, breathlessness, chest tightness, and coughing, particularly at night or in the early morning. These episodes are usually associated with widespread but variable airflow obstruction that is often reversible either spontaneously or with treatment. The inflammation also causes an associated increase in the existing bronchial hyperresponsiveness (BHR) to a variety of stimuli. Reversibility of airflow limitation may be incomplete in some patients with asthma.

This definition encompasses the important heterogeneity of the clinical presentation of asthma by describing the scientific and clinically accepted characteristics of asthma.

The complete chapter, learning objectives, and other resources can be found at **www.pharmacotherapyonline.com**.

EPIDEMIOLOGY

1 An estimated 22.9 million persons in the United States have asthma (about 7.7% of the population).[3] Asthma is the most common chronic disease among children in the United States, with approximately 6.7 million children affected. The prevalence rate is highest in children 5 to 17 years of age at 10.0%.[3] In the United States, as in other industrialized countries, the prevalence of asthma increased through the 1980s and 1990s but appears to be leveling off. Asthma accounts for 1.6% of all ambulatory care visits (10.6 million physician office visits and 1.2 million hospital outpatient visits) and resulted in 440,000 hospitalizations and 1.7 million emergency department (ED) visits in 2006 (both declined from peaks in the 1990s).[3] Asthma is the third leading cause of preventable hospitalization in the United States; however, hospitalizations have decreased over the past 10 years to 14.9 per 10,000 population with 33% reported in children less than 15 years of age. Asthma accounts for more than 12.8 million missed school days per year.[3] In young children (0–10 years of age), the risk of asthma is greater in boys than in girls, becomes about equal during puberty, and then is greater in women than in men.[3]

Ethnic minorities continue to share the burden of asthma disproportionately. African Americans have a 39% higher prevalence than whites.[3] African Americans are 3 times as likely to be hospitalized and approximately 3 times more likely to die from asthma than whites.[3] In addition, African Americans and Puerto Ricans living in inner cities are four times more likely to experience ED visits than whites.[3] However, Hispanics in general have lower prevalence and hospitalization rates than African Americans or whites.

The estimated direct medical cost of asthma in the United States in 2007 was $14.7 billion.[3] The societal burden of asthma (indirect medical expenditures: loss of productivity and death) in the United States was $5.0 billion. Prescription drugs were the largest

single direct medical expenditure at $6.2 billion; however, the combined costs of emergency care of acute asthma exacerbations makes up 36% of direct medical costs.[3]

The natural history of asthma is still not well defined. Although asthma can occur at any time, it is principally a pediatric disease, with most patients being diagnosed by 5 years of age and up to 50% of children having symptoms by 2 years of age.[2] Between 30% and 70% of children with asthma will improve markedly or become symptom-free by early adulthood; chronic disease persists in about 30% to 40% of patients, and generally 20% or less develop severe chronic disease.[2] Predictors of persistent adult asthma include atopy, onset during school age, and presence of BHR.[4] Diminished lung growth may occur in some children (approximately 10%) with asthma.[2]

In adults, most longitudinal studies have suggested a more rapid rate of decline in lung function in asthmatics than in nonasthmatic normals, primarily reflected in forced expiratory volume in 1 second (FEV_1).[4] However, the annual decline in FEV_1 is less than in smokers or in patients with a diagnosis of emphysema. In general, individuals with less frequent asthma attacks and normal lung function on initial assessment have higher remission rates, whereas smokers have the lowest remission and highest relapse rates.[4] The level of BHR tends to predict the rate of decline in FEV_1, with a greater decline with high levels of BHR.[2] Thus airways obstruction in asthma not only may become irreversible but also may worsen over time owing to airway remodeling (see below).[2,4] However, most patients do not die from long-term progression of their disease and their life-span is not different from the general population.[4]

As with prevalence and morbidity, mortality from acute exacerbations of asthma has been decreasing over the past 10 years, with 3,565 deaths reported in 2007.[3] Despite the relatively low number of asthma deaths, 80% to 90% are preventable.[2] Most deaths from asthma occur outside the hospital, and death is rare after hospitalization. The most common cause of death from asthma is inadequate assessment of the severity of airways obstruction by the patient or physician and inadequate therapy. The most common cause of death in hospitalized patients is also inadequate or inappropriate therapy. Thus the key to prevention of death from asthma, as advocated by the U.S. National Asthma Education and Prevention Program (NAEPP), is education.[2]

ETIOLOGY

1 Epidemiologic studies strongly support the concept of a genetic predisposition plus environmental interaction to the development of asthma, yet the picture remains complex and incomplete.[5] Genetic factors account for 60% to 80% of the susceptibility. Asthma represents a complex genetic disorder in that the asthma phenotype is likely a result of polygenic inheritance or different combinations of genes. Initial searches focused on establishing links between atopy (genetically determined state of hypersensitivity to environmental allergens) and asthma, but more recent genome-wide searches have found linkages with genes for metalloproteinases (e.g., *ADAM33*) and handling bacteria (*CHI3L1*).[5] Although genetic predisposition to atopy is a significant risk factor for developing asthma, not all atopic individuals develop asthma, nor do all patients with asthma exhibit atopy. Disparate phenotypes of asthma (progressive or remodelled versus non-progressive) are likely genetically determined.[5]

1 Environmental risk factors for the development of asthma include socioeconomic status, family size, exposure to secondhand tobacco smoke in infancy and in utero, allergen exposure, urbanization, respiratory syncytial virus infection, and decreased exposure to common childhood infectious agents.[6,7] The "hygiene hypothesis" proposes that genetically susceptible individuals develop allergies and asthma by allowing the allergic immunologic system (Th_2 lymphocytes) to develop instead of the system to fight infections (Th_1 lymphocytes) and may explain the increase of asthma in developed countries.[6,7] The first 2 years of life appear to be most important for the exposures to produce an alteration in the immune response system.[6] The hygiene hypothesis is supported by studies demonstrating a lower risk for asthma in children who are exposed to high levels of bacteria or endotoxin, in those with a large number of older siblings, in those with early enrollment into child care, in those with exposure to cats and dogs early in life, or in those with exposure to fewer antibiotics.[5–7]

Risk factors for early (<3 years of age) recurrent wheezing associated with viral infections include low birth weight, male gender, and parental smoking. However, this early pattern is due to smaller airways, and these risk factors are not necessarily risk factors for asthma in later life.[6] Atopy is the predominant risk factor for children to have continued asthma.[6,7] Asthma can begin in adults later in life. Occupational asthma in previously healthy individuals emphasizes the effect of environment on the development of asthma.[8] The heterogeneity of the asthma phenotype appears most obvious when listing the diverse triggers of bronchospasm[2,6] (Table 33–1). The various triggers have relative degrees of importance from patient to patient. Environmental exposures are the most important precipitants of severe asthma exacerbations[9] (see Table 33–1). Epidemics of severe asthma in cities have followed exposures to high concentrations of aeroallergens.[9] Viral respiratory tract infections remain the single most significant precipitant of severe asthma in children and are an important trigger in adults as well.[9] Other possible factors include air pollution, sinusitis, food preservatives, and drugs.

TABLE 33-1 List of Agents and Events Triggering Asthma

Respiratory infection
Respiratory syncytial virus (RSV), rhinovirus, influenza, parainfluenza, *Mycoplasma pneumonia, Chlamydia*
Allergens
Airborne pollens (grass, trees, weeds), house-dust mites, animal danders, cockroaches, fungal spores
Environment
Cold air, fog, ozone, sulfur dioxide, nitrogen dioxide, tobacco smoke, wood smoke
Emotions
Anxiety, stress, laughter
Exercise
Particularly in cold, dry climate
Drugs/preservatives
Aspirin, NSAIDs (cyclooxygenase inhibitors), sulfites, benzalkonium chloride, nonselective β-blockers
Occupational stimuli
Bakers (flour dust); farmers (hay mold); spice and enzyme workers; printers (arabic gum); chemical workers (azo dyes, anthraquinone, ethylenediamine, toluene diisocyanates, polyvinyl chloride); plastics, rubber, and wood workers (formaldehyde, western cedar, dimethylethanolamine, anhydrides)

PATHOPHYSIOLOGY

2 The major characteristics of asthma include a variable degree of airflow obstruction (related to bronchospasm, edema, and mucus hypersecretion), BHR, and airways inflammation (Fig. 33–1). To understand the pathogenetic mechanisms that underlie the many phenotypes of asthma, it is critical to identify factors that initiate, intensify, and modulate the inflammatory response of the airways and to determine how these processes produce the characteristic airway abnormalities.

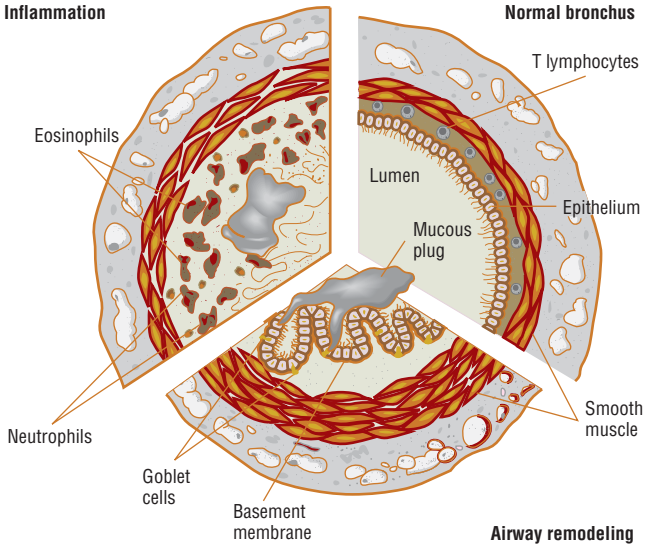

FIGURE 33-1. Representative illustration of the pathology found in the asthmatic bronchus compared with a normal bronchus (*upper right*). Each section demonstrates how the lumen is narrowed. Hypertrophy of the basement membrane, mucus plugging, smooth muscle hypertrophy, and constriction contribute (*lower section*). Inflammatory cells infiltrate, producing submucosal edema, and epithelial desquamation fills the airway lumen with cellular debris and exposes the airway smooth muscle to other mediators (*upper left*).

ACUTE INFLAMMATION

Inhaled allergen challenge models contribute most to our understanding of acute inflammation in asthma.[7] Inhaled allergen challenge in allergic patients leads to an early-phase reaction that, in some cases, may be followed by a late-phase reaction. The activation of cells bearing allergen-specific IgE initiates the early-phase reaction. It is characterized by the rapid activation of airway mast cells and macrophages leading to the rapid release of proinflammatory mediators such as histamine, eicosanoids, and reactive oxygen species that induce contraction of airway smooth muscle, mucus secretion, and vasodilatation.[7] The bronchial microcirculation has an essential role in this inflammatory process. Inflammatory mediators induce microvascular leakage with exudation of plasma in the airways.[7] Acute plasma protein leakage induces a thickened, engorged, and edematous airway wall and a consequent narrowing of the airway lumen. Plasma exudation may compromise epithelial integrity, and the presence of plasma in the lumen may reduce mucus clearance.[7] Plasma proteins also may promote the formation of exudative plugs mixed with mucus and inflammatory and epithelial cells. Together these effects contribute to airflow obstruction (Fig. 33–1).

The late-phase inflammatory reaction occurs 6 to 9 hours after allergen provocation and involves the recruitment and activation of eosinophils, $CD4^+$ T cells, basophils, neutrophils, and macrophages.[7] There is selective retention of airway T cells, the expression of adhesion molecules, and the release of selected proinflammatory mediators and cytokines involved in the recruitment and activation of inflammatory cells.[7] The activation of T cells after allergen challenge leads to the release of T-helper cell type 2 (Th_2)–like cytokines that may modulate the late-phase response.[7] The release of preformed cytokines by mast cells is the likely initial trigger for the early recruitment of inflammatory cells that then recruit and induce the more persistent involvement by T cells.[7] The enhancement of nonspecific BHR usually can be demonstrated after the late-phase reaction but not after the early-phase reaction following allergen or occupational challenge.

CHRONIC INFLAMMATION

Airways inflammation has been demonstrated in all forms of asthma, and an association between the extent of inflammation and the clinical severity of asthma has been demonstrated in selected studies.[7] It is accepted that both central and peripheral airways are inflamed.

In asthma, all cells of the airways are involved and become activated (Fig. 33–2). Included are eosinophils, T cells, mast cells, macrophages, epithelial cells, fibroblasts, and bronchial smooth muscle cells. These cells also regulate airway inflammation and initiate the process of remodeling by the release of cytokines and growth factors.[7,10]

Epithelial Cells

Bronchial epithelial cells participate in mucociliary clearance and removal of noxious agents; however, they also enhance inflammation by releasing eicosanoids, peptidases, matrix proteins, cytokines, and nitric oxide (NO).[7,10] Epithelial cells can be activated by IgE-dependent mechanisms, viruses, pollutants, or histamine. In asthma, especially fatal asthma, extensive epithelial shedding occurs. The functional consequences of epithelial shedding may include heightened airways responsiveness, altered permeability of the airway mucosa, depletion of epithelial-derived relaxant factors, and loss of enzymes responsible for degrading proinflammatory neuropeptides. The integrity of airway epithelium may influence the sensitivity of the airways to various provocative stimuli. Epithelial cells also may be important in the regulation of airway remodeling and fibrosis.[7,10]

Eosinophils

Eosinophils play an effector role in asthma by releasing proinflammatory mediators, cytotoxic mediators, and cytokines.[7] Circulating eosinophils migrate to the airways by cell rolling, through interactions with selectins, and eventually adhere to the endothelium through the binding of integrins to adhesion proteins (vascular cell adhesion molecule 1 [VCAM-1] and intercellular adhesion molecule 1 [ICAM-1]). As eosinophils enter the matrix of the membrane, their survival is prolonged by interleukin 5 (IL-5) and granulocyte-macrophage colony-stimulating factor (GM-CSF). On activation, eosinophils release inflammatory mediators such as leukotrienes and granule proteins to injure airway tissue.[7]

Lymphocytes

Mucosal biopsy specimens from patients with asthma contain lymphocytes, many of which express surface markers of inflammation. There are two types of T-helper $CD4^+$ cells. Type 1 T-helper (Th_1) cells produce IL-2 and interferon-γ (IFN-γ), both essential for cellular defense mechanisms. Th_2 cells produce cytokines (IL-4, -5, and -13) that mediate allergic inflammation. It is known that Th_1 cytokines inhibit the production of Th_2 cytokines, and vice versa. It is hypothesized that allergic asthmatic inflammation results from a Th_2-mediated mechanism (an imbalance between Th_1 and Th_2 cells).[7] However, more recently it has been observed that there exists a low Th_2 cytokine phenotype of asthma in adults that appears more resistant to usual therapies for asthma.[11]

Th_1 and Th_2 Cell Imbalance

The T-cell population in the cord blood of newborn infants is skewed toward a Th_2 phenotype.[6,7] The extent of the imbalance between Th_1 and Th_2 cells (as indicated by diminished IFN-γ production) during the neonatal phase may predict the subsequent development of allergic disease, asthma, or both. It has been

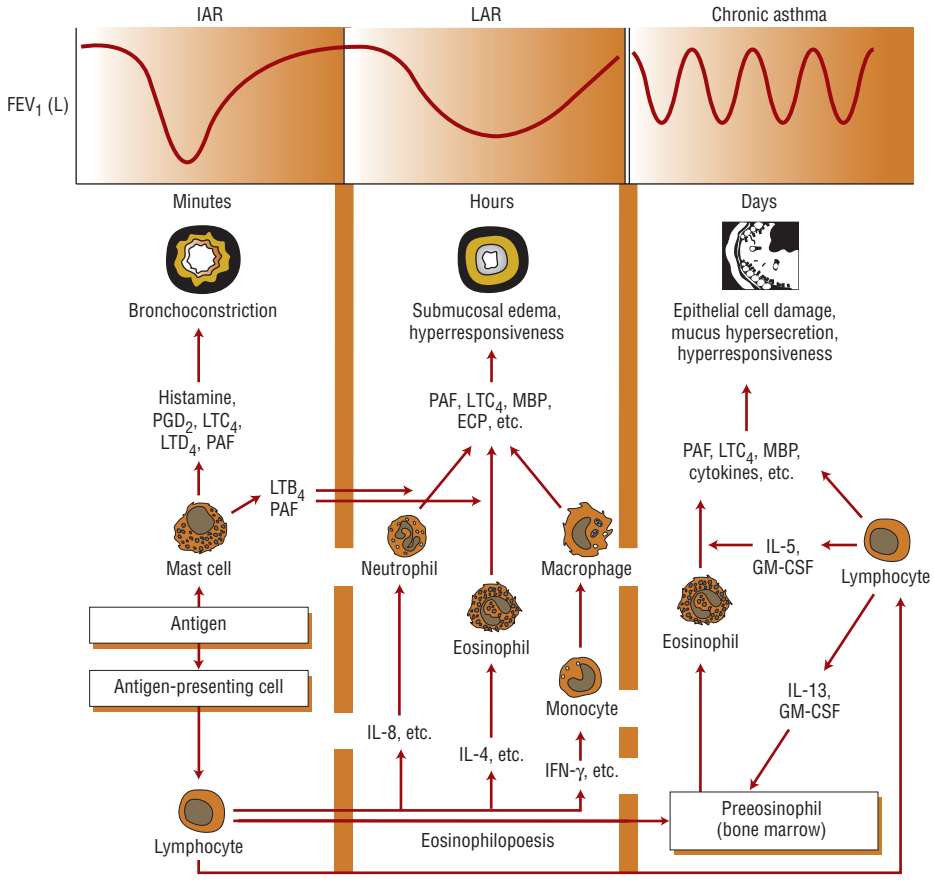

FIGURE 33-2. Diagrammatic presentation of the relationship between inflammatory cells, lipid and preformed mediators, inflammatory cytokines, and proposed pathogenesis and clinical presentation in asthma. See text for details. PG, prostaglandin; LT, leukotriene; PAF, platelet-activating factor; IL, interleukin; MBP, major basic protein; GM-CSF, granulocyte-macrophage colony-stimulating factor.

suggested that infants at high risk of asthma and allergies should be exposed to stimuli that upregulate Th_1-mediated responses in order to restore the balance during a critical time in the development of the immune system and the lungs.[6]

The basic premise of the hygiene hypothesis is that the newborn's immune system needs timely and appropriate environmental stimuli to create a balanced immune response. Factors that enhance Th_1-mediated responses include: infection with *Mycobacterium tuberculosis,* measles virus, and hepatitis A virus; increased exposure to infections through contact with older siblings; and day care attendance during the first 6 months of life. Restoration of the balance between Th_1 and Th_2 cells may be impeded by frequent administration of oral antibiotics, with concomitant alterations in gastrointestinal flora. Other factors favoring the Th_2 phenotype include residence in an industrialized country, urban environment exposure, diet, and sensitization to house dust mites and cockroaches.[6] Immune "imprinting" may begin in utero by transplacental transfer of allergens and cytokines.

Mast Cells

Mast cell degranulation is important in the initiation of immediate responses following exposure to allergens.[2] Mast cells reside throughout the walls of the respiratory tract, and increased numbers of these cells (3- to 5-fold) have been described in the airways of allergic asthmatics.[7] Once binding of allergen to cell-bound IgE occurs, mediators such as histamine; eosinophil and neutrophil chemotactic factors; leukotrienes (LTs) C_4, D_4, and E_4; prostaglandins; platelet-activating factor (PAF); and others are released from mast cells (see Fig. 33–2). Histologic examination has revealed decreased numbers of granulated mast cells in the airways of patients who have died from acute asthma attacks, suggesting that mast cell degranulation is a contributing factor. Sensitized mast cells are also activated by osmotic stimuli to account for exercise-induced bronchospasm (EIB).[12]

Alveolar Macrophages

The primary function of alveolar macrophages in the normal airway is to serve as "scavengers," engulfing and digesting bacteria and other foreign materials. Macrophages are found in large and small airways, ideally located for affecting the asthmatic response. A number of mediators produced and released by macrophages have been identified, including PAF, LTB_4, LTC_4, and LTD_4.[7] Additionally, alveolar macrophages are able to produce neutrophil chemotactic factor and eosinophil chemotactic factor, which in turn amplify the inflammatory process.

Neutrophils

The role of neutrophils in the pathogenesis of asthma remains somewhat unclear because they normally may be present in the airways and usually do not infiltrate tissues showing chronic allergic inflammation despite the potential to participate in late-phase inflammatory reactions. However, high numbers of neutrophils have been observed in the airways of patients who died from sudden-onset fatal asthma and in those with severe disease.[13] This suggests that neutrophils may play a pivotal role in the disease process, at least in some patients with long-standing or corticosteroid-resistant asthma.[13] The neutrophil also can be a source for a variety of mediators, including PAF, prostaglandins, thromboxanes, and leukotrienes, that contribute to BHR and airway inflammation.[13]

Fibroblasts and Myofibroblasts

Fibroblasts are found frequently in connective tissue. Human lung fibroblasts may behave as inflammatory cells on activation by IL-4

and IL-13. The myofibroblast may contribute to the regulation of inflammation via the release of cytokines and to tissue remodeling. In asthma, myofibroblasts are increased in numbers beneath the reticular basement membrane, and there is an association between their numbers and the thickness of the reticular basement membrane.[7,10]

Inflammatory Mediators

Associated with asthma for many years, histamine is capable of inducing smooth muscle constriction and bronchospasm and is thought to play a role in mucosal edema and mucus secretion.[2] Lung mast cells are an important source of histamine. The release of histamine can be stimulated by exposure of the airways to a variety of factors, including physical stimuli (airway drying with exercise) and relevant allergens.[7] Histamine is involved in acute bronchospasm following allergen exposure; however, other mediators such as leukotrienes are also involved.

Besides histamine release, mast cell degranulation releases interleukins, proteases, and other enzymes that activate the production of other mediators of inflammation. Several classes of important mediators, including arachidonic acid and its metabolites (i.e., prostaglandins, leukotrienes, and PAF), are derived from cell membrane phospholipids.

Once arachidonic acid is released, it can be metabolized by the enzyme cyclooxygenase to form prostaglandins. Prostaglandin D_2 is a potent bronchoconstricting agent, however it is unlikely to produce sustained effects and its role in asthma remains to be determined. Similarly, prostaglandin $F_{2\alpha}$ is a potent bronchoconstrictor in patients with asthma and can enhance the effects of histamine.[2,7] However, its pathophysiologic role in asthma is unclear. Another cyclooxygenase product, prostacyclin (prostaglandin I_2), is known to be produced in the lung and may contribute to inflammation and edema owing to its effects as a vasodilator.

Thromboxane A_2 is produced by alveolar macrophages, fibroblasts, epithelial cells, neutrophils, and platelets within the lung.[7] Thromboxane A_2 may have several effects, including bronchoconstriction, involvement in the late asthmatic response, and involvement in the development of airway inflammation and BHR.

The 5-lipoxygenase pathway of arachidonic acid metabolism is responsible for the production of the *cysteinyl leukotrienes*.[7] Leukotriene C_4, LTD_4, and LTE_4 are released during inflammatory processes in the lung. Leukotrienes D_4 and E_4 share a common receptor (LTD_4 receptor) that, when stimulated, produces bronchospasm, mucus secretion, microvascular permeability, and airway edema, whereas LTB_4 is involved with granulocyte chemotaxis.

Thought to be produced by macrophages, eosinophils, and neutrophils within the lung, PAF is involved in the mediation of bronchospasm, sustained induction of BHR, edema formation, and chemotaxis of eosinophils.[7]

Adhesion Molecules

Adhesion molecules are glycoproteins that facilitate infiltration and migration of inflammatory cells to the site of inflammation. Adhesion molecules have additional functions involved in the inflammatory process aside from promoting cell adhesion, including activation of cells and cell–cell communication, and promoting cellular migration and infiltration.[2] The many adhesion molecules are divided into families on the basis of their chemical structure. These families are the integrins, cadherins, immunoglobulin supergene family, selectins, vascular adressins, and carbohydrate ligands.[7] Those thought to be important in inflammation include the integrins, immunoglobulin supergene family, selectins, and carbohydrate ligands, including ICAM-1 and VCAM-1.[7] Adhesion molecules are found on a variety of cells, such as neutrophils, monocytes, lymphocytes, basophils, eosinophils, granulocytes, platelets, endothelial cells, and epithelial cells, and can be expressed or activated by the many inflammatory mediators present in asthma.[7]

CLINICAL CONSEQUENCES OF CHRONIC INFLAMMATION

Chronic inflammation is associated with nonspecific BHR and increases the risk of asthma exacerbations. Exacerbations are characterized by increased symptoms and worsening airways obstruction over a period of days or even weeks, and rarely hours. Hyperresponsiveness of the airways to physical, chemical, and pharmacologic stimuli is a hallmark of asthma.[2] BHR also occurs in some patients with chronic bronchitis and allergic rhinitis.[2] Normal healthy subjects also may develop a transient BHR after viral respiratory infections or ozone exposure. However, the degree of BHR in patients with asthma is quantitatively greater than in other populations. Bronchial responsiveness of the general population fits a unimodal distribution that is skewed toward increased reactivity; individuals with clinical asthma represent the extreme end of this distribution. The degree of BHR within asthma correlates with its clinical course and medication requirement necessary to control symptoms.[2] Patients with mild symptoms or in remission demonstrate lower levels of BHR.

The current understanding is that the BHR seen in asthma is at least in part due to and correlative with the extent of airways inflammation.[2] Airways remodeling also correlates somewhat with BHR.[10]

REMODELING OF THE AIRWAYS

Acute inflammation is a beneficial, nonspecific response of tissues to injury and generally leads to repair and restoration of the normal structure and function. In contrast, asthma represents a chronic inflammatory process of the airways followed by healing that in some may result in altered structure referred to as *remodeling*.[10] Repair involves replacement of injured tissue by parenchymal cells of the same type and replacement by connective tissue and its maturation into scar tissue. In asthma, remodeling presents as extracellular matrix fibrosis, an increase in smooth muscle and mucus gland mass, and angiogenesis.[10]

The precise mechanisms of remodeling of the airways are under intense study. Airways remodeling is of concern because it may represent an irreversible process that can have more serious sequelae such as the development of chronic obstructive pulmonary disease (COPD).[2,10] Observations in children with asthma indicate that some loss of lung function may occur during the first 5 years of life.[6] Importantly, no current therapies have been shown to alter either early decreased lung growth or later progressive loss of lung function.

MUCUS PRODUCTION

The mucociliary system is the lung's primary defense mechanism against irritants and infectious agents. Mucus, composed of 95% water and 5% glycoproteins, is produced by bronchial epithelial glands and goblet cells.[7] The lining of the airways consists of a continuous aqueous layer controlled by active ion transport across the epithelium in which water moves toward the lumen along the concentration gradient. Catecholamines and vagal stimulation enhance the ion transport and fluid movement. Mucus transport depends on its viscoelastic properties. Mucus that is either too watery or too viscous will not be transported optimally. The exudative

inflammatory process and sloughing of epithelial cells into the airway lumen impair mucociliary transport. The bronchial glands are increased in size and the goblet cells are increased in size and number in asthma. Expectorated mucus from patients with asthma tends to have a high viscosity. The mucus plugs in the airways of patients who died in status asthmaticus are tenacious and tend to be connected by mucous strands to the goblet cells. Asthmatic airways also may become plugged with casts consisting of epithelial and inflammatory cells. Although it is tempting to speculate that death from asthma attacks is a result of the mucus plugging resulting in irreversible obstruction, there is no direct evidence for this. Autopsies of asthmatics who died from other causes have shown similar pathology. In addition, some patients who have died of sudden severe asthma did not show the characteristic mucus plugging on necropsy.[7]

AIRWAY SMOOTH MUSCLE

The smooth muscle of the airways does not form a uniform coat around the airways but is wrapped around in a connecting network best described as a spiral arrangement.[14] The muscle contraction displays a sphincteric action that is capable of completely occluding the airway lumen. The airway smooth muscle extends from the trachea through the respiratory bronchioles. When expressed as a percentage of wall thickness, the smooth muscle represents 5% of the large central airways and up to 20% of the wall thickness in the bronchioles. Total smooth muscle mass decreases rapidly past the terminal bronchioles to the alveoli, so the contribution of smooth muscle tone to airway diameter in this region is relatively small. In the large airways of asthmatics, smooth muscle may account for 11% of the wall thickness. It is possible that the increased smooth muscle mass of the asthmatic airways is important in magnifying and maintaining BHR in persistent disease. However, it appears that the hypertrophy and hyperplasia are secondary processes caused by chronic inflammation and are not the primary cause of BHR.[14]

NEURAL CONTROL/NEUROGENIC INFLAMMATION

The airway is innervated by parasympathetic, sympathetic, and nonadrenergic inhibitory nerves.[2] Parasympathetic innervation of the smooth muscle consists of efferent motor fibers in the vagus nerves and sensory afferent fibers in the vagus and other nerves.[14] The normal resting tone of human airway smooth muscle is maintained by vagal efferent activity. Maximum bronchoconstriction mediated by vagal stimulation occurs in the small bronchi and is absent in the small bronchioles. The nonmyelinated C fibers of the afferent system lie immediately beneath the tight junctions between epithelial cells lining the airway lumen.[14] These endings probably represent the irritant receptors of the airways. Stimulation of these irritant receptors by mechanical stimulation, chemical and particulate irritants, and pharmacologic agents such as histamine produces reflex bronchoconstriction.[7]

The nonadrenergic, noncholinergic (NANC) nervous system has been described in the trachea and bronchi. Substance P, neurokinin A, neurokinin B, and vasoactive intestinal peptide (VIP) are the best characterized neurotransmitters in the NANC nervous system.[7] VIP is an inhibitory neurotransmitter. Inflammatory cells in asthma can release peptidases that can degrade VIP, producing exaggerated reflex cholinergic bronchoconstriction. NANC excitatory neuropeptides such as substance P and neurokinin A are released by stimulation of C-fiber sensory nerve endings. The NANC system may play an important role in amplifying inflammation in asthma by releasing NO.

NITRIC OXIDE

NO is produced by cells within the respiratory tract. It has been thought to be a neurotransmitter of the NANC nervous system.[15] Endogenous NO is generated from the amino acid L-arginine by the enzyme NO synthase.[15] There are three isoforms of NO synthase. One isoform is induced in response to proinflammatory cytokines, inducible NO synthase (iNOS), in airway epithelial cells and inflammatory cells of asthmatic airways.[15] NO produces smooth muscle relaxation in the vasculature and bronchials; however, it appears to amplify the inflammatory process and is unlikely to be of therapeutic benefit. Investigations measuring the fraction of exhaled NO (FeNO) concentrations have suggested that it may be a useful measure of ongoing lower airways inflammation in patients with asthma and for guiding asthma therapy.[15]

CLINICAL PRESENTATION

CHRONIC ASTHMA

3 Classic asthma is characterized by episodic dyspnea associated with wheezing; however, the clinical presentation of asthma is as diverse as the number of triggering events (see Clinical Presentation: Chronic Ambulatory Asthma). Although wheezing is the characteristic symptom of asthma, the medical literature is replete with the warning that "not all that wheezes is asthma." A wheeze is a high-pitched, whistling sound created by turbulent airflow through an obstructed airway, so any condition that produces significant obstruction can result in wheezing as a symptom. In addition, "all of asthma does not wheeze" is an equally justifiable warning. Patients may present with a chronic persistent cough as their only symptom.[2]

CLINICAL PRESENTATION: CHRONIC AMBULATORY ASTHMA

General

- Asthma is a disease of exacerbation and remission, so the patient may not have any signs or symptoms at the time of exam.

Symptoms

- The patient may complain of episodes of dyspnea, chest tightness, coughing (particularly at night), wheezing, or a whistling sound when breathing. These often occur in association with exercise, but also occur spontaneously or in association with known allergens.

Signs

- Expiratory wheezing on auscultation, dry hacking cough, or signs of atopy (allergic rhinitis and/or eczema) may occur.

Laboratory

- Spirometry demonstrates obstruction (reduced FEV_1/FVC) with reversibility following inhaled β_2-agonist administration (at least a 12% improvement in FEV_1).

Other Diagnostic Tests

- A fall in FEV_1 of at least 15% following 6 minutes of near maximal exercise. Elevated eosinophil count and IgE concentration in blood. Elevated FeNO (greater than 20 ppb in children less than 12 years of age and greater than 25 ppb in adults). Positive methacholine challenge (PC_{20} FEV_1 less than 12.5 mg/mL) or mannitol challenge (FEV_1 decrease of at least 15% from baseline after 635 mg or less).

TABLE 33-2 Sample Questions[a] for the Diagnosis and Initial Assessment of Asthma

A "yes" answer to any question suggests that an asthma diagnosis is likely. In the past 12 months.…

- Have you had a sudden severe episode or recurrent episodes of coughing, wheezing (high-pitched whistling sounds when breathing out), chest tightness, or shortness of breath?
- Have you had colds that "go to the chest" or take more than 10 days to get over?
- Have you had coughing, wheezing, or shortness of breath during a particular season or time of the year?
- Have you had coughing, wheezing, or shortness of breath in certain places or when exposed to certain things (e.g., animals, tobacco smoke, perfumes)?
- Have you used any medications that help you breathe better? How often?
- Are your symptoms relieved when the medications are used?

In the past 4 weeks, have you had coughing, wheezing, or shortness of breath.…

- At night that has awakened you?
- Upon awakening?
- After running, moderate exercise, or other physical activity?

[a]These questions are recommended by the NAEPP but have not been formally validated.

There is no single diagnostic test for asthma. The diagnosis is based primarily on a good history[2] (Table 33–2). The patient may have a family history of allergy or asthma or have symptoms of allergic rhinitis.[2] Reversibility of airways obstruction following administration of a short-acting inhaled β_2-agonist provides confirmation but is not by itself diagnostic. Patients with normal values of spirometry can be challenged by exercise or substances that produce bronchoconstriction, such as methacholine, to determine if they have BHR, but again, positive challenges are not diagnostic. Newer tests of inflammation in the airways such as induced sputum eosinophil counts and FeNO measurements are consistent with but not diagnostic of asthma.

Asthma has a widely variable presentation from chronic daily symptoms to only intermittent symptoms. The intervals between symptoms can be days, weeks, months, or years. Asthma also can vary as to its severity, the intrinsic intensity of the disease process. Severity is most easily and directly measured in a patient who is not currently receiving asthma treatment. The NAEPP has provided a means of classifying asthma severity that is broken down into two domains: impairment and risk.[2] This classification system is individualized for 3 age groups (0–4 years, 5–11 years, and ≥12 years) and summarized in Table 33–3. The intermittent and/or chronic nature of symptoms does not necessarily determine the severity of symptoms during exacerbations. Asthma severity is determined by lung function, symptoms, nighttime awakenings, and interference with normal activity prior to therapy. Patients can present with a range from intermittent symptoms that require no medications or only occasional use of short-acting inhaled β_2-agonists to severe persistent asthma symptoms despite treatment with multiple medications.

ACUTE SEVERE ASTHMA

Uncontrolled asthma, with its inherent variability, can progress to an acute state where inflammation, airways edema, excessive mucus accumulation, and severe bronchospasm result in a profound airways narrowing that is poorly responsive to usual bronchodilator therapy[2,9] (see Clinical Presentation: Acute Severe

TABLE 33-3 Classifying Asthma Severity for Patients who are not Currently Taking Long-Term Control Medications

		Children 0–4 Years and 5–11 Years of Age			
			Persistent		
	Components	**Intermittent**	**Mild**	**Moderate**	**Severe**
Impairment	Symptoms	≤2 days/wk	>2 days/wk but not daily	Daily	Throughout the Day
	Nighttime Awakenings (0–4 y)	0	1–2 × mo	3–4 × mo	>1 × wk
	(5–11 y)	≤2 × mo	3–4 × mo	>1 × wk, but not nightly	Often 7 × wk
	SABA Use for Sx control	≤2 days/wk	>2 days/wk but not daily	Daily	Several times per day
	Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited
	Lung function	FEV_1 >80%	FEV_1 >80%	FEV_1 60%–80%	FEV_1 <60%
	(5–11 y)	FEV_1/FVC >85%	FEV_1/FVC >80%	FEV_1/FVC 75%–80%	FEV_1/FVC <75%
Risk	**Exacerbations**	**Intermittent**	**Persistent**

Asthma). Although this progression is the most common scenario, some patients experience rapid onset or hyper-acute attacks.[2,9] Hyperacute attacks are associated with neutrophilic as opposed to eosinophilic infiltration and resolve rapidly with bronchodilator therapy, suggesting that smooth muscle spasm is the major pathogenic mechanism.[9,13] In most cases, ED visits for acute severe asthma represent the failure of an adequate therapeutic regimen for persistent asthma. Underutilization of antiinflammatory drugs and excessive reliance on short-acting inhaled β_2-agonists are the major risk factors for severe exacerbations.[2] However, frequent exacerbations may represent a specific phenotype of asthma.[9] A blunted perception of airways obstruction may predispose certain individuals to fatal asthma attacks.[2]

CLINICAL PRESENTATION: ACUTE SEVERE ASTHMA

General

- An episode can progress over several days or hours (usual scenario) or progresses rapidly over 1 to 2 hours.

Symptoms

- The patient is anxious in acute distress and complains of severe dyspnea, shortness of breath, chest tightness, or burning. The patient is only able to say a few words with each breath. Symptoms are unresponsive to usual measures (short-acting inhaled β_2-agonist administration).

Signs

- Signs include expiratory and inspiratory wheezing on auscultation (breath sounds may be diminished with very severe obstruction), dry hacking cough, tachypnea, tachycardia, pale or cyanotic skin, hyperinflated chest with intercostal and supraclavicular retractions, and hypoxic seizures if very severe.

Laboratory

- PEF and/or FEV_1 less than 40% of normal predicted values. Decreased arterial oxygen (PaO_2), and O_2 saturations by pulse oximetry (SaO_2 less than 90% on room air is severe). Decreased arterial or capillary CO_2 if mild, but in the normal range or increased in moderate to severe obstruction.

Other Diagnostic Tests

- Blood gases to assess metabolic acidosis (lactic acidosis) in severe obstruction. Complete blood count if there are signs of infection (fever and purulent sputum). Serum electrolytes as therapy with β_2-agonist and corticosteroids can lower serum potassium, magnesium, and phosphate, and increase glucose. Chest radiograph if signs of consolidation on auscultation.

EXERCISE-INDUCED BRONCHOSPASM

During vigorous exercise, pulmonary function measurements (FEV_1 and peak expiratory flow [PEF]) in patients with asthma increase during the first few minutes but then begin to decrease after 6 to 8 minutes (Fig. 33–3).[2] Exercise-induced bronchospasm (EIB) is defined as a drop in FEV_1 of 15% or greater from baseline (pre-exercise value).[2] Most studies suggest that many patients with persistent asthma experience EIB.[2] The exact pathogenesis of EIB is unknown, but heat loss and/or water loss from the central airways appears to play an important role.[12] EIB is provoked more easily in cold, dry air; alternatively, warm, humid air can blunt or block it.[12] Studies have demonstrated increased plasma histamine, cysteinyl leukotrienes, prostaglandins and tryptase concentrations during EIB, suggesting a role for mast cell degranulation.[12] These findings have led to the development of inhaled mannitol, an osmotic agent as an indirect pharmacologic bronchoprovocation test to assist in the diagnosis of asthma.[16]

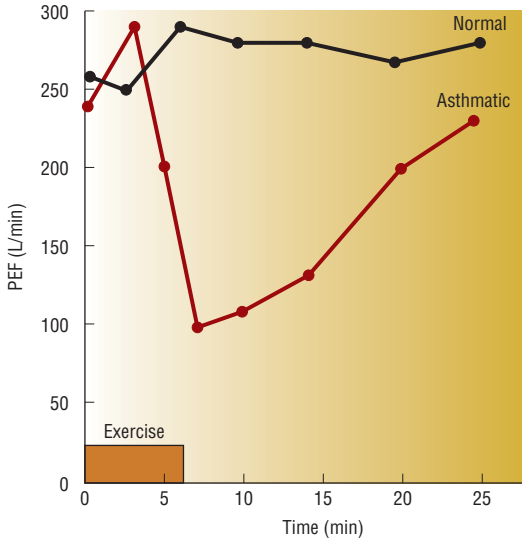

FIGURE 33-3. Typical responses to exercise in a normal subject and an asthmatic subject. Note the initial bronchodilation. PEF, peak expiratory flow.

A refractory period following EIB lasts up to 3 hours after exercise in some patients. During this period, repeat exercise of the same intensity produces either no decrease in pulmonary function or a drop of less than 50% of the initial response.[12] This refractory period is thought to be caused by an acute depletion of mast cell mediators and time required for their repletion. Patients with known refractoriness to exercise will still respond to histamine, so acute hyporesponsiveness of airway smooth muscle does not appear to be a factor.[12]

EIB is believed to be a reflection of the increased BHR of asthmatics. A correlation, though not perfect, exists between EIB and reactivity to histamine, methacholine, and mannitol.[12,16] Other patient groups with BHR (e.g., after viral infection, cystic fibrosis, or allergic rhinitis) show bronchoconstriction after exercise to a lesser degree (5%–10% drops) than patients with asthma (15%–40% drops).[12] Patients will not always demonstrate the same sensitivity. During periods of remission, a decreased sensitivity to the same degree of exercise is often observed. Finally, a number of children and adults with EIB are otherwise normal, without symptoms or abnormal pulmonary function except in association with exercise.[2] Elite athletes have a higher prevalence of EIB than the general population.[12]

NOCTURNAL ASTHMA

❸ Worsening of asthma during sleep is referred to as *nocturnal asthma.* Patients with nocturnal asthma exhibit significant falls in pulmonary function between bedtime and awakening.[2] Typically, their lung function reaches a nadir at 3 to 4 AM. Although the pathogenesis of this phenomenon is unknown, it has been associated with diurnal patterns of endogenous cortisol secretion and circulating epinephrine.[2] Direct evidence for an inflammatory component to nocturnal asthma includes increased circulating histamine and activated eosinophils and leukotriene excretion at night associated with increased BHR to methacholine.[2]

Numerous other factors that may affect nocturnal worsening of asthma, including allergies and improper environmental control, gastroesophageal reflux, obstructive sleep apnea, and sinusitis, also must be considered when evaluating these patients.[2] Most experts consider nocturnal symptoms to be a sign of inadequately treated persistent asthma.[2] Awakening from nocturnal asthma is a sensitive indicator of both severity and asthma control.[2]

FACTORS CONTRIBUTING TO ASTHMA SEVERITY

VIRAL RESPIRATORY INFECTIONS

Viral respiratory infections are primarily responsible for exacerbations of asthma, particularly in children under age 10.[9] Infants are particularly susceptible to airways obstruction and wheezing with viral infections because of their small airways. The most common cause of exacerbations in both children and adults is the common rhinovirus.[9] Other viruses isolated include respiratory syncytial virus (RSV), parainfluenza virus, coronavirus, and influenza viruses. Certain viruses (RSV and parainfluenza virus) are capable of inducing specific IgE antibodies, and rhinovirus can activate eosinophils directly in asthmatics.[7] The increase in asthma symptoms and BHR that occurs may last for days or weeks following resolution of the symptoms of the viral infection. Evidence does not support a beneficial effect of influenza vaccine for preventing asthma exacerbations from subsequent influenza infections.[17]

ENVIRONMENTAL AND OCCUPATIONAL FACTORS

Agents and events and the mechanisms that are known to trigger asthma are listed in Table 33–1.[2] The general mechanisms are unknown but presumably are the result of epithelial damage and inflammation in the airway mucosa. Ozone and sulfur dioxide, common components of air pollution, have been used to induce BHR in animals. Exposure to 0.2 ppm ozone for 2 to 3 hours can induce bronchoconstriction and increase BHR in asthmatics.[2,8] Sulfur dioxide in the ambient atmosphere is highly irritating and presumably induces bronchoconstriction through mast cell or irritant-receptor involvement.[2] Asthma produced by repeated prolonged exposure to industrial inhalants is a significant health problem. It has been estimated that occupational asthma accounts for 2% of all asthmatic persons.[8] Persons with occupational asthma have the typical symptoms of asthma with cough, dyspnea, and wheeze. Typically, the symptoms are related to work place exposure and improve on days off and during vacations.[8] In some instances, symptoms may persist even after termination of exposure.[8]

STRESS, DEPRESSION, AND PSYCHOSOCIAL FACTORS IN ASTHMA

Observational studies demonstrate an association between increased stress and worsening asthma, but the role is not clearly defined.[2] Bronchoconstriction from psychological factors appears to be mediated primarily through excess parasympathetic input. Atropine has been shown to block experimental psychogenic bronchoconstriction. It is most important to emphasize to both patients and parents that asthma is not an emotional disease; however, coping skills may benefit the patient who becomes emotionally distraught during an asthma attack.

RHINITIS/SINUSITIS

Disorders of the upper respiratory tract, particularly rhinitis and sinusitis, have been linked with asthma for many years. As many as 40% to 50% of asthmatics have abnormal sinus radiographs.[2] However, chronic sinusitis may just represent a nonbacterial coexisting condition with allergic asthmatics because the histologic changes in the paranasal sinuses are similar to those seen in the lung and nose.[2] Treatment of upper airway disease may optimize overall asthma control. The mechanism by which sinusitis aggravates asthma is unknown. The treatment of allergic rhinitis with intranasal corticosteroids and cromolyn but not antihistamines will reduce BHR in asthmatic patients.[2] It has been postulated that transport of mucus chemotactic factors and inflammatory mediators from nasal passages during allergic rhinitis into the lung may accentuate BHR.

GASTROESOPHAGEAL REFLUX DISEASE

Symptoms of gastroesophageal reflux disease (GERD) as well as asymptomatic reflux are common in both children and adults who have asthma.[2] Nocturnal asthma may be associated with nighttime reflux.[2] Reflux of acidic gastric contents into the esophagus is thought to initiate a vagally mediated reflex bronchoconstriction.[2] Also of concern is that most medications that decrease airways smooth muscle tone may have a relaxant effect on gastroesophageal sphincter tone. However, treatment of reflux in asthma patients has produced inconsistent results on asthma control.[2,18] The current recommendation is to initiate standard antireflux therapy in those patients exhibiting symptoms of reflux.[2]

FEMALE HORMONES AND ASTHMA

Premenstrual worsening of asthma has been reported in as many as 30% to 40% of women in some studies, whereas worsening of pulmonary functions has been reported even in women not aware of worsening symptoms.[19] The pathophysiology is uncertain because estrogen replacement in postmenopausal women has been shown to worsen asthma, whereas estradiol and progesterone administration have been variably reported to improve or have no effect on asthma in women with premenstrual asthma.[19,20] The clinical significance of menstruation-related asthma is still unclear because some studies have reported that up to 50% of ED visits by women were premenstrual, whereas others have reported no association with menstrual phase.[19,20] In general, BHR and symptoms improve in asthmatic women during pregnancy.[2,19]

FOODS, DRUGS, AND ADDITIVES

Documentation in the literature of food allergens as triggers for asthma is not available.[2] However, additives, specifically sulfites used as preservatives, can trigger life-threatening asthma exacerbations. Beer, wine, dried fruit, and open salad bars in particular have high concentrations of metabisulfites.[2] Severe oral corticosteroid-dependent patients should be warned about ingesting foods processed with sulfites. Another additive producing bronchospasm is benzalkonium chloride, which is found as a preservative in some nebulizer solutions of antiasthmatic drugs.[21]

Aspirin and other nonsteroidal antiinflammatory drugs can precipitate an attack in up to 20% of adults and 5% of children with asthma.[22] The mechanism is related to cyclooxygenase inhibition, and 5-lipoxygenase inhibition can alter dose-response but not completely block the symptoms.[22] The prevalence increases with age and severity of asthma.[2] The greatest frequency occurs in severe corticosteroid-resistant asthmatics in their fourth and fifth decades who also have perennial rhinitis and nasal polyposis (presence of several polyps).[22] Other drugs that do not precipitate bronchospasm but which prevent its reversal are the nonselective β-blocking agents.[2]

NUTRITIONAL FACTORS

Epidemiologic data suggest that obesity increases the prevalence of asthma and may reduce asthma control.[23] Lung volume and tidal

volume are reduced in obesity promoting airway narrowing. Obesity also produces low-grade systemic inflammation that may act on the lung to worsen asthma.[23] The mechanism is likely the release of adipose-derived pro-inflammatory mediators such as IL-6, IL-10, eotaxin, tumor necrosis factor-α, transforming growth factors-β_1, C-reactive protein, leptin, and adiponectin or a result of common predisposing dietary factors. Although not all studies find relationship between body mass index and asthma control, management of asthma in obese patients should include weight loss measures.[24]

More recently it has been shown that children with vitamin D insufficiency are at greater risk of uncontrolled asthma (increased hospitalizations, BHR and eosinophil counts).[25] Vitamin D helps regulate T-cells and improves their secretion of antiinflammatory cytokines in response to corticosteroids.[25]

TREATMENT

Asthma

AEROSOL THERAPY FOR ASTHMA

4 5 Aerosol delivery of drugs for asthma has the advantage of being site-specific and thus enhancing the therapeutic ratio.[2,26] Inhalation of short-acting β_2-agonists provides more rapid bronchodilation than either parenteral or oral administration, as well as the greatest degree of protection against EIB and other challenges.[2] Inhaled corticosteroids have been developed with rapid oral and systemic clearance to enhance lung activity and reduce systemic activity. Specific agents (e.g., cromolyn, formoterol, salmeterol, and ipratropium bromide) are only effective by inhalation.[26] Therefore, an understanding of aerosol drug delivery is essential to optimal asthma therapy. Table 33–4 lists the factors determining lung deposition of therapeutic aerosols.

TABLE 33-4 Factors Determining Lung Deposition of Aerosols

Device	Device Factors	Patient Factors
Metered-dose inhaler (MDI)	Canister held inverted Formulation (CFC, HFA, solution, suspension) Actuator cleanliness Addition of a spacer device	Inspiratory flow (slow, deep) Breath-holding Coordinating actuation with inhalation Priming and shaking the device
Dry-powder inhaler (DPI)	Device cleanliness Resistance to inhalation Humidity	Inspiratory flow (deep, forceful) Tilting head back Maintaining parallel to ground once activated
Jet nebulizer (small volume)	Volume fill (3–6 mL) Gas flow (6–12 L/min) Dead-space volume Open vs closed system Thumb-activating valve Mouthpiece vs facemask	Inspiratory flow (slow, deep) Breath-holding Tapping nebulizer
Ultrasonic nebulizer	Volume fill Not effective for suspensions Mouthpiece vs facemask	Inspiratory flow (slow, deep) Breath-holding Tapping nebulizer
Spacer device	Volume (≥650 mL) One-way valves Holding chamber vs open-ended Anti-static linning Mouthpiece vs facemask	Inspiratory flow (slow, deep) Time between actuation and inhalation (<5 s) Cleaning with detergent to reduce static Multiple actuations decrease delivery Coordination of actuation and inhalation for the simple open-tube spacers

Device Determinants of Delivery

Devices used to generate therapeutic aerosols include jet nebulizers, ultrasonic nebulizers, metered-dose inhalers (MDIs), and dry-powder inhalers (DPIs). The single most important device factor determining the site of aerosol deposition is particle size.[26] Devices for delivering therapeutic aerosols generate particles with aerodynamic diameters from 0.5 to 35 microns.[26] Particles larger than 10 microns deposit in the oropharynx, particles between 5 and 10 microns deposit in the trachea and large bronchi, particles 1 to 5 microns in size reach the lower airways, and particles smaller than 0.5 microns act as a gas and are exhaled. In asthma, the airways, not the alveoli, are the target for delivery. Respirable particles are deposited in the airways by three mechanisms: (1) inertial impaction, (2) gravitational sedimentation, and (3) Brownian diffusion.[26] The first two mechanisms are the most important for therapeutic aerosols and probably are the only factors that can be manipulated by patients.

Each delivery device within a classification generates specific aerosol characteristics, so extrapolation of delivery data from one device cannot be applied to the other devices in the class. For instance, MDIs can deliver 15% to 50% of the actuated dose; DPIs, 10% to 30% of the labeled dose; and nebulizers, 2% to 15% of the starting dose.[26] MDIs and DPIs are portable and convenient, unlike jet nebulizers. Small portable ultrasonic nebulizers have also been developed. MDIs consist of a pressurized canister with a metering valve; the canister contains active drug, low-vapor-pressure propellants such as chlorofluorocarbon (CFC) or hydrofluoroalkane (HFA), cosolvents, and/or surfactants.[26] The international ban on the production and use of CFCs (due to their ozone layer–depleting properties) will result in no CFC propelled MDIs available in the United States by December 31, 2011. With any change in the components of an MDI, the Food and Drug Administration (FDA) considers it to be a new drug that requires stability, safety, and efficacy studies prior to approval. The drug is either in solution or a suspended micronized powder. In order to disperse the suspension for accurate delivery, the canister must be shaken. The metering chamber measures a liquid volume, and therefore, the device must be held with the valve stem downward so that the chamber is covered with liquid[26] (Fig. 33–4). When the canister is actuated, the device releases the propellant and drug in a forceful spray whose particles are large (mass median aerodynamic diameter [MMAD] = 45 microns) [26] (see Fig. 33–4). As evaporation occurs, the particle size is reduced to a final MMAD of 0.5 to 5.5 microns depending on the MDI. The aerosol cloud extends about 6 inches beyond the MDI at the lowest MMAD.[26] Each MDI has different conditions for storage and durations to expiration so the pharmacist must become familiar with and counsel the patient on these factors.

The breath-actuated MDI Autohaler is cocked with a lever to "load" the dose of medication, a baffle is opened by inspiratory

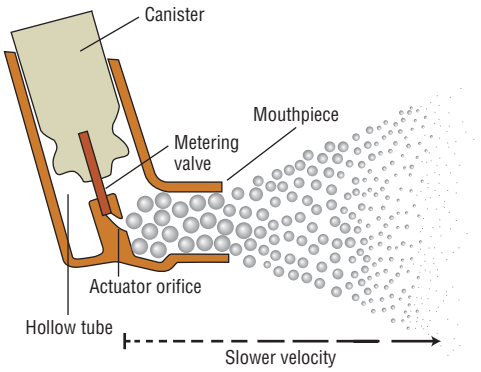

FIGURE 33-4. Illustration of a metered-dose inhaler demonstrating the particle size difference as the aerosol cloud extends outward.

TABLE 33-5 Characteristics of Various Inhalation Devices

Device	Drugs	Breath Activated	Dose Counter	Other Excipients	Disadvantages
CFC MDI	All classes	No	No	Propellants, surfactants	Requires coordination of actuation and inhalation Large pharyngeal deposition Difficult to teach
HFA-MDI	Albuterol	No	No/Yes	Propellants, surfactants, cosolvents	Same as CFC MDI
	Levalbuterol	No	No		
	Corticosteroids	No	No		
	ICS/LABA combinations	No	No		
Autohaler MDI	Pirbuterol	Yes	No	CFC propellant, surfactant	Requires rapid inhalation to activate
MDI plus valved holding chamber	All classes	No	No		More expensive than MDI alone; less portable; some payers will not pay; inconsistent effect on delivery; nonstatic preferred
Jet nebulizers	All classes	No	–	Preservatives in some solutions	Significant interbrand variability; expensive and time consuming; less efficient than MDIs; contamination possible; preparations may be light and temperature sensitive (short shelf-life)
Ulrasonic nebulizer	Cromolyn solution, short acting β_2-agonist solutions	No	–	Preservatives in some solutions	Same as for jet nebulizers plus cannot be used for suspensions
Flexhaler	Budesonide	Yes	Yes	Lactose filler	Requires high inspiratory flow (60 L/min). Pharyngeal deposition. Not approved for <6 years of age
Diskus	Fluticasone Salmeterol Fluticasone/salmeterol	Yes	Yes	Lactose filler	Not approved for <4 years of age Requires inspiratory flow of 30–60 L/min
Aerolizer	Formoterol	Yes	–	Lactose filler	Single-dose capsules. Not approved for <5 years of age Requires flow of 30–60 L/min
Twisthaler	Mometasone	Yes	Yes	Lactose filler	Not approved for <4 years of age

pressure, and the dose is expelled from the canister metering chamber.[26] While the need for hand-lung coordination for proper actuation is reduced significantly with breath-actuated MDIs, these devices do not allow the use of a spacer device.

Spacer devices are used frequently with an MDI to decrease oropharyngeal deposition and enhance lung delivery.[2] However, not all spacer devices produce similar effects. The design of spacers varies from simple open-ended tubes that separate the MDI from the mouth to valved holding chambers (VHCs) with one-way valves that open during inhalation (the preferred system). A VHC allows evaporation of the propellant prior to inhalation permitting a greater number of drug particles to achieve a respirable droplet size. VHC use also allows inhalation after actuation of the MDI, obviating the need for good hand-lung coordination.[26] Additionally, the large particles that normally would deposit in the oropharynx "rain out" in the spacer.[26] All the available spacers significantly reduce oropharyngeal deposition from MDIs, with the VHCs being superior to the open-ended tubes.[26] This reduction in oropharyngeal deposition is an important factor in reducing local adverse effects (e.g., hoarseness and thrush) from inhaled corticosteroids.[26] The change in lung delivery depends on both the MDI and the drug, where one spacer device may enhance delivery with one MDI preparation and decrease delivery with others.[26] The use of VHCs is less likely to enhance delivery from HFA propelled MDIs. Finally, over time, holding chambers can build up static electricity that attracts small particles to the sides of the chamber, significantly reducing aerosol availability. Some spacers should be washed weekly with household detergent with a single rinse and allowed to drip dry.[26] Other VHCs have been developed with antistatic lining.

Dry micronized powders can be inhaled directly into the lung. A number of DPIs are now available for use in the United States.[26] Currently, there are no generic DPIs as each drug plus device has its own patent. Each DPI has unique characteristics with advantages and disadvantages (Table 33–5). The primary advantage of DPIs is that they are breath actuated and require minimal hand-lung coordination and are thus easier to teach patients proper technique.[26] Some DPIs are more flow-dependent than others.[26] Thus, similar to MDIs and spacers, delivery data from one DPI cannot be extrapolated to another.

Nebulizers come in two basic types, the jet nebulizer and the ultrasonic nebulizer. Jet nebulizers produce an aerosol from a liquid solution or suspension placed in a cup. A tube connected to a stream of compressed air or oxygen flows up through the bottom and draws the liquid up an adjacent open-ended tube.[26] The air and liquid strike a baffle, creating a droplet cloud that is then inhaled.[26] Ultrasonic nebulizers produce an aerosol by vibrating liquid lying above a transducer at speeds of about 1 mHz.[26] Both produce similar degrees of lung deposition, with the exception that ultrasonic nebulizers are ineffective for nebulizing currently available micronized suspensions.[26] The aerosol output and lung delivery vary significantly among the commercially available jet nebulizers even when operated in the same manner.[26] Increasing fill volume will increase the total amount of drug delivered; however, it also will take longer for the patient to nebulize the dose.[26] The MMAD of the droplets is related directly to the gas flow, with flows of 5 to 12 L/min providing an aerosol cloud with an MMAD of 4 to 8 microns for most jet nebulizers.[26] Each jet nebulizer comes with its optimal operating instructions.

Patient Determinants of Delivery (See Table 33–4)

6 7 The most important patient factor determining aerosol deposition is inspiratory flow.[2,26] High inspiratory flows increase the degree of deposition owing to impaction of particles of any

size, thereby increasing deposition centrally (i.e., throat and large airways) and decreasing peripheral deposition. Optimal inspiratory flow for most MDIs is slow and deep (approximately 30 L/min or 5 seconds for a full inhalation).[2] In general, DPIs require higher inspiratory flows (≥60 L/min) and a change in inhalation technique (i.e., deep, forceful inspiration) for optimal dispersion of the powder, which, in turn, increases the amount of drug delivered to the larger central airways.[26] However, this difference in delivery may not produce clinically significant differences.[26] Patients should be cautioned not to exhale into DPIs because this causes loss of dose and moistens the dry powder, causing aggregation into larger particles. Patient factors that cannot be controlled include interpatient variability in airway geometry (particularly the differences between children and adults)[26] and the effects of bronchospasm, edema, and mucus hypersecretion. Mild obstruction increases aerosol deposition; however, severe obstruction probably leads to increased central deposition from impaction.[26] The absolute delivery to the lung is not as important as consistency of delivery, assuming that a sufficient dose to produce the desired therapeutic effect is achieved. No single inhalation device is the best for all patients. Table 33–5 lists the differing characteristics of inhalation devices.

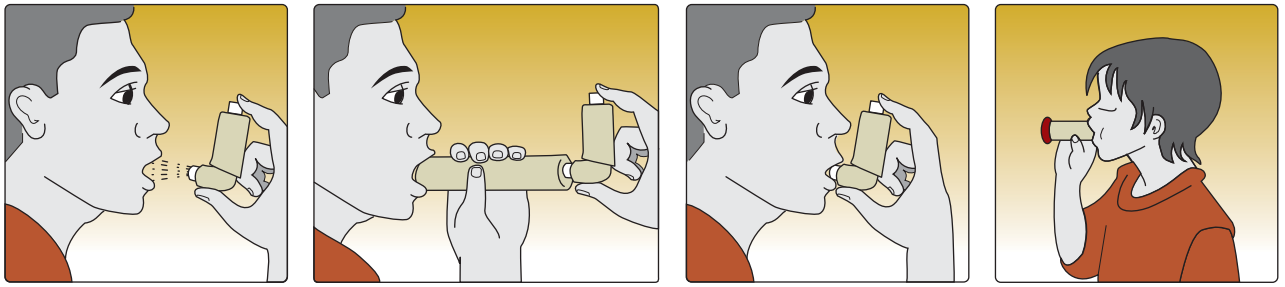
Appropriate inhalation technique is essential to achieve optimal drug delivery and therapeutic effect.[2] The components are illustrated in Figure 33–5. Approximately 50% to 80% of a dose from MDIs and DPIs impacts on the oropharynx and is then swallowed; the rest is either left in the device or exhaled.[26] It is important that actuation occurs during inhalation, although the time during inspiration is unimportant.[2,26] Although radiolabeled studies with MDIs indicate improved delivery by holding the actuator 2 to 3 cm in front of an open mouth to allow more evaporation and less impaction, physiologic studies with bronchodilators have failed to document an advantage for this method.[2,26] Many patients do not use their MDIs optimally, and patient instruction with demonstration is the most effective means of improving inhaler technique.[2,26] Even with instruction, up to 30% of patients, particularly young children and the elderly, cannot master the use of an MDI. For these patients, attachment of a VHC to the MDI or use of a breath-actuated MDI can improve efficacy significantly.[2,26] However addition of a VHC offers no advantage in patients who can use an MDI optimally alone.[26] Mouth rinsing following treatment with MDI- and DPI-inhaled corticosteroids is important to minimize local effects and oral absorption.[2,26]

Delivery from high-resistance DPIs is more flow-dependent than from low-resistance DPIs. Thus, younger children and possibly elderly adults will have more variability in delivery from high resistance devices.[26] Most children younger than 4 years of age cannot generate a sufficient inspiratory flow to use DPIs. Young children (<4 years) and infants generally require the use of a facemask attached to either an MDI plus VHC or nebulizer. The use of a facemask results in a reduction in lung delivery due to the portion of the aerosol inhaled nasally so the doses of drugs used in these patients is often not decreased.

Steps for Using Your Inhaler

Please demonstrate your inhaler technique at every visit.

1. Remove the cap and hold inhaler upright.
2. Shake the inhaler.
3. Tilt your head back slightly and breathe out slowly.
4. Position the inhaler in one of the following ways (B is acceptable for those who have difficulty with A or C. C is required for breath-activated inhalers):



A Open mouth with inhaler 1 to 2 inches away.

B Use spacer/holding chamber (that is recommended especially for young children and for people using corticosteroids).

C In the mouth.

D NOTE: Inhaled dry powder capsules require a different inhalation technique. To use a dry powder inhaler, it is important to close the mouth tightly around the mouthpiece of the inhaler and to inhale rapidly.

5. Press down on the inhaler to release medication as you start to breathe in slowly.
6. Breathe in slowly (3 to 5 seconds).
7. Hold your breath for 10 seconds to allow the medicine to reach deeply into your lungs.
8. Repeat puff as directed. Waiting 1 minute between puffs may permit second puff to penetrate your lungs better.
9. Spacers/holding chambers are useful for all patients. They are particularly recommended for young children and older adults and for use with corticosteroids.

Avoid common inhaler mistakes. Follow these inhaler tips:

- Breathe out *before* pressing your inhaler.
- Inhale *slowly*.
- Breathe in through your mouth, not your nose.
- Press down on your inhaler at the *start* of inhalation (or within the first second of inhalation).
- Keep inhaling as you press down on inhaler.
- Press your inhaler only *once* while you are inhaling (one breath for each puff).
- Make sure you breathe in evenly and deeply.

NOTE: Other inhalers are becoming available in addition to those illustrated above. Different types of inhalers require different techniques.

FIGURE 33-5. Instructions for inhaler use from the adapted NAEPP Expert Panel Report 2. *http://www.nhlbi.nih.gov/guidelines/archives/epr-2/index.htm.*

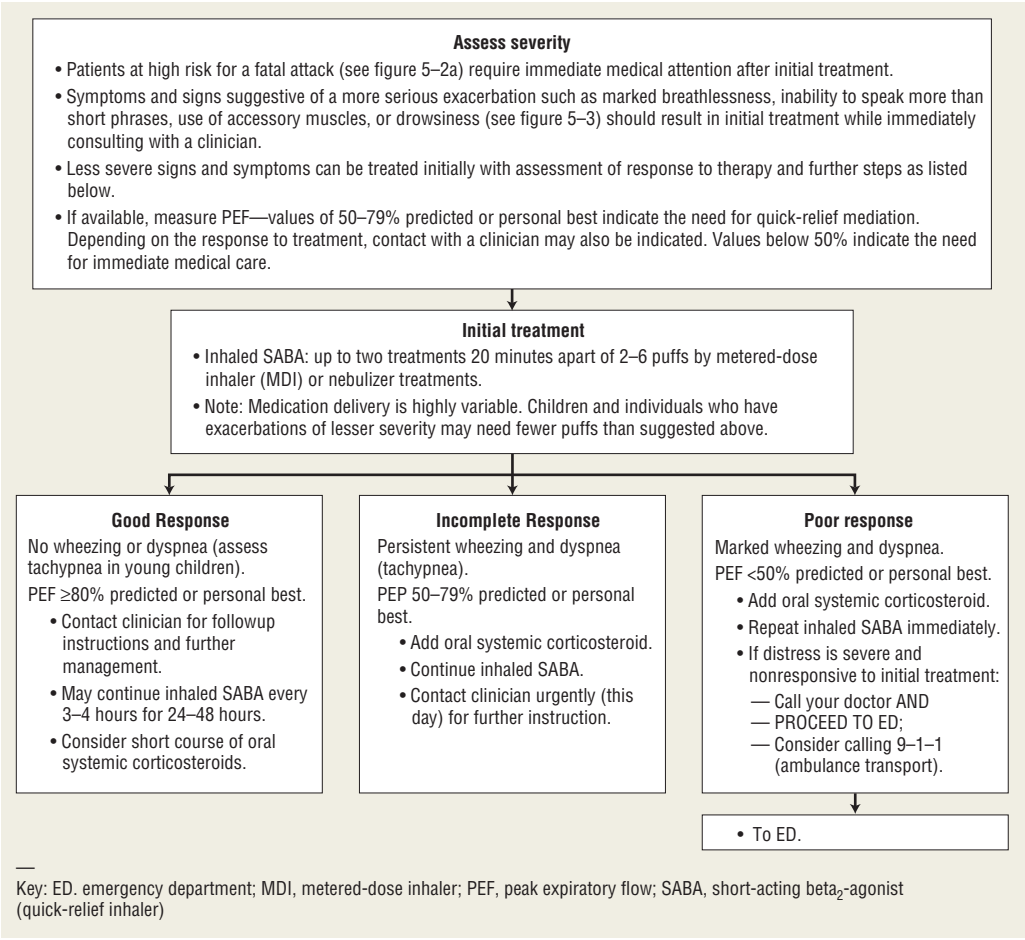


FIGURE 33-6. Home management of acute asthma exacerbation. Patients at risk for asthma-related death should receive immediate clinical attention after initial treatment. Additional therapy may be required. *(From reference 2.)*

TREATMENT

Acute Severe Asthma

The primary goal is prevention of life-threatening asthma by early recognition of signs of deterioration and early intervention. As such, the principal goals of treatment include:[2]

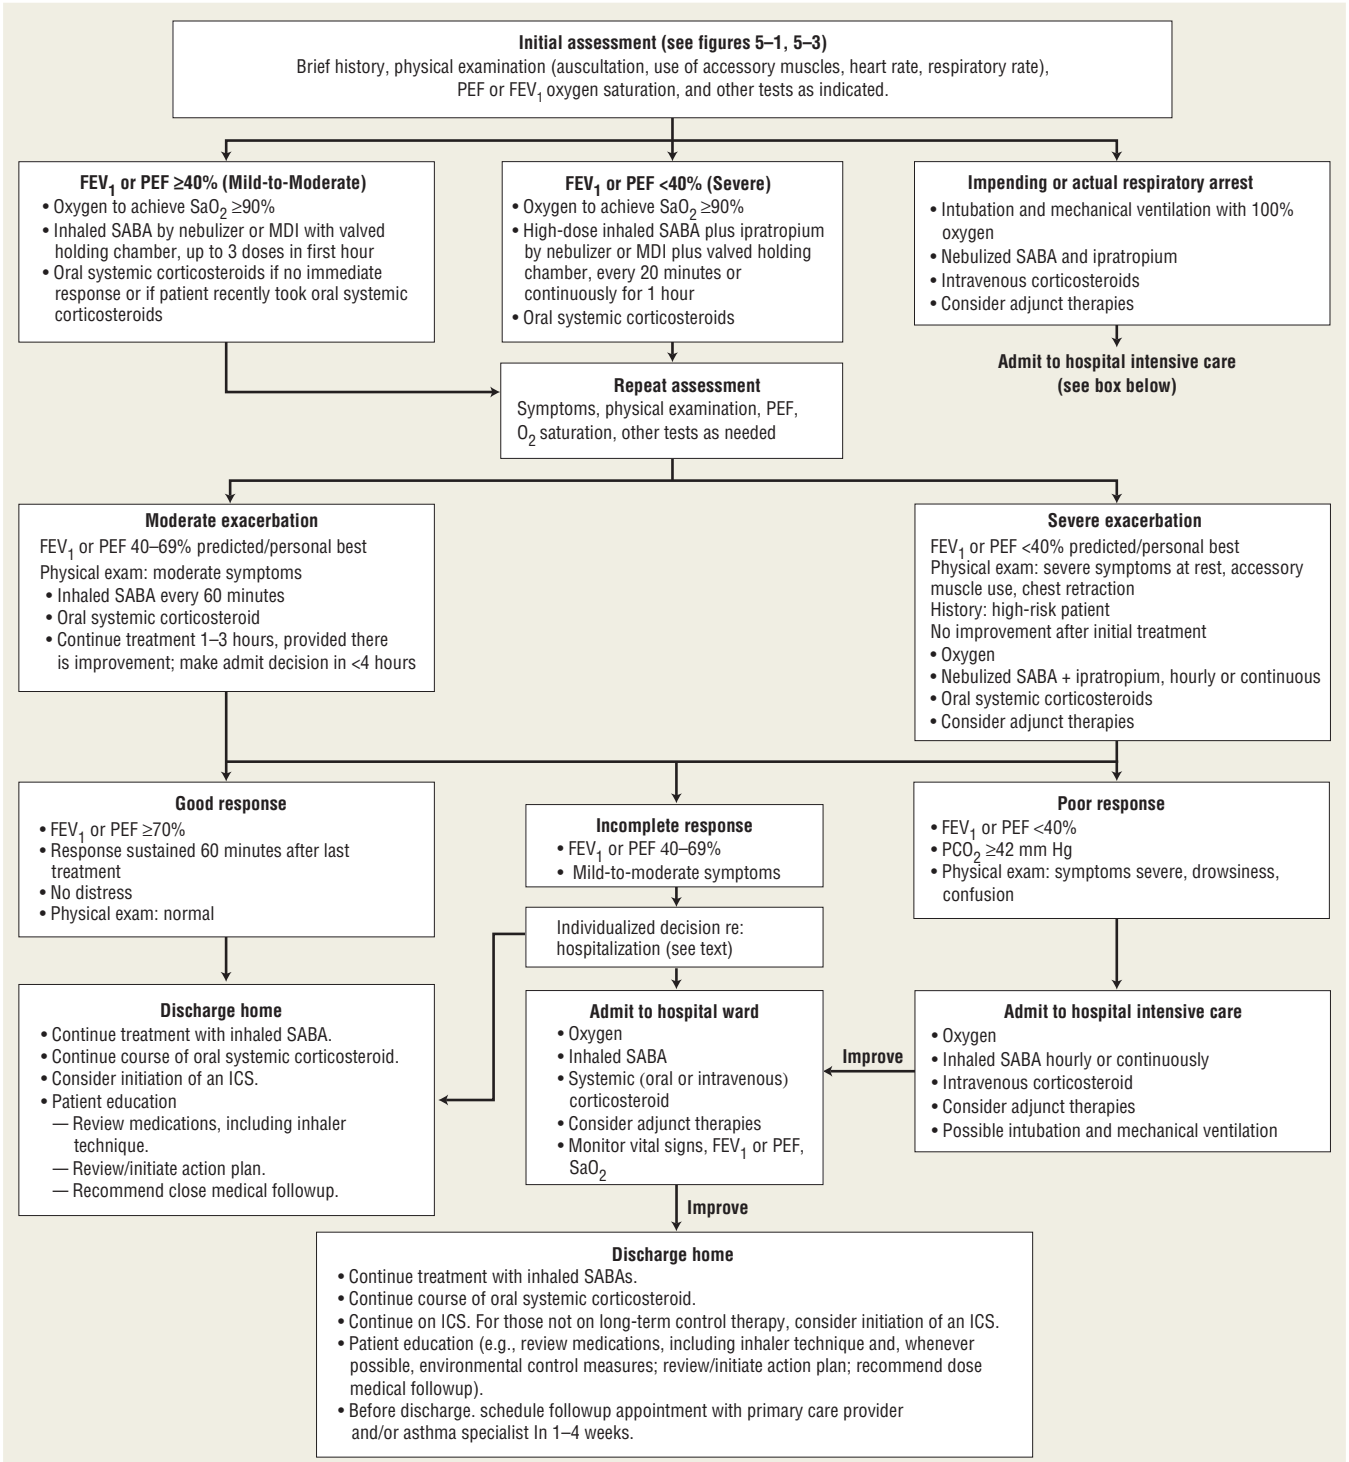
- Correction of significant hypoxemia
- Rapid reversal of airflow obstruction
- Reduction of the likelihood of relapse of the exacerbation or future recurrence of severe airflow obstruction
- Development of a written asthma action plan in case of a further exacerbation

These goals are best achieved by early initiation or intensification of treatment and close monitoring of objective measures of oxygenation and lung function.[2] Early response to treatment as measured by the improvement in FEV_1 at 30 minutes following inhaled β_2-agonists is the best predictor of outcome.[2,27] Providing adequate oxygen supplementation to maintain oxygen (O_2) saturations above 90% (or >95% in pregnant women and those who have coexistent heart disease) is essential. In children younger than 6 years of age, in whom lung function measures are difficult to obtain, a combination of objective (e.g., oxygen saturation, capillary CO_2, respiratory rate, and heart rate) and subjective measures may be used to assess severity.[2]

The primary therapy of acute exacerbations is pharmacologic, which includes short-acting inhaled β_2-agonists and, depending on the severity, systemic corticosteroids, inhaled ipratropium and O_2 (Figs. 33–6 and 33–7).[2] It is important that therapy not be delayed, so the history and physical examination should be obtained while initial therapy is being provided. Patients at risk for life-threatening exacerbations require special attention. Risk factors include: a history of previous severe asthma exacerbations (e.g., hospitalizations, intubations, or hypoxic seizures); difficulty perceiving asthma symptoms or severity of exacerbations; comorbidities (e.g., cardiac disease, other chronic lung disease, illicit drug use, or major psychosocial/psychiatric history); use of more than two canisters per month of short-acting inhaled β_2-agonists; and current intake of oral corticosteroids or recent withdrawal from oral corticosteroids.[2]

A complete blood count may be appropriate for patients with fever or purulent sputum, but modest leukocytosis is common in asthma exacerbations due to viral infection or secondary to corticosteroid administration. Chest radiography is not recommended for routine assessment but should be obtained for patients suspected of a complicating cardiopulmonary process or another pulmonary process (pneumothorax or pulmonary consolidation).[2] Serum electrolytes should be monitored if high-dose continuous inhaled or systemic β_2-agonists are to be used because they can produce transient decreases in potassium, magnesium, and phosphate.[2] Measurement of serum electrolytes is also prudent in patients who take diuretics regularly and in patients with coexistent cardiovascular disease. The combination of high-dose β_2-agonists and systemic corticosteroids occasionally may result in excessive elevations of glucose and lactic acid.[2]

Initial response should be achieved within minutes, and most patients experience significant improvement within the first 30 to



Key: FEV_1, forced expiratory volume in 1 second; ICS, inhaled corticosteroid; MDI, metered dose inhaler; PCO_2, partial pressure carbon dioxide; PEF, peak expiratory flow; SABA, short-acting $beta_2$-agonist; SaO_2, oxygen saturation

FIGURE 33-7. Emergency department and hospital care of acute asthma exacerbations. *(From reference 2.)*

60 minutes of therapy, with most patients doubling their FEV_1 or PEF.[2] In patients ultimately admitted to the hospital, only a 10% to 20% improvement is seen within the first 2 hours. Hypoxemia, primarily a result of ventilation-perfusion mismatch, is immediately correctable by low-flow oxygen.[2] While reversal of lung function into the normal range may take 12 to 24 hours, complete restoration takes much longer—up to 3 to 7 days.[2] A strategy to prevent recurrence includes systemic corticosteroids and symptom or PEF monitoring.[2] It is essential to provide the patient with a written self-management action plan for dealing with exacerbations. Patients at risk for severe exacerbations should be taught how to use a peak-flow meter and monitor morning peak flows at home.[2] In young children, an increased respiratory rate, increased heart rate, and inability to speak more than one or two words between breaths are signs of severe obstruction.[2] Oxygen saturations by pulse oximetry and peak flows should be measured in all patients not completely responding to initial intensive inhaled β_2-agonist therapy. Initially, on admission, the peak flows or clinical symptoms should be monitored every 2 to 4 hours. Prior to discharge from the ED or hospital, the patient should be given a sufficient supply

TABLE 33-6 Dosages of Drugs of Acute Severe Exacerbations of Asthma in the Emergency Department or Hospital

Medications	Dosages ≥12 Years Old	Dosages <12 Years Old	Comments
Inhaled β-agonists			
Albuterol nebulizer soln. (5 mg/mL, 0.63 mg/3 mL, 1.25 mg/3 mL, 2.5 mg/3 mL)	2.5–5 mg every 20 min for 3 doses, then 2.5–10 mg every 1–4 h as needed, or 10–15 mg/h continuously	0.15 mg/kg (minimum dose 2.5 mg) every 20 min for 3 doses, then 0.15–0.3 mg/kg up to 10 mg every 1–4 h as needed, or 0.5 mg/kg/h by continuous nebulization	Only selective β_2-agonists are recommended. For optimal delivery, dilute aerosols to minimum of 4 mL at gas flow of 6–8 L/min. Use face mask if <4 years.
Albuterol MDI (90 mcg/puff)	4–8 puffs every 30 min up to 4 h, then every 1–4 h as needed	4–8 puffs every 20 min for 3 doses, then every 1–4 h as needed	In patients in severe distress, nebulization is preferred; use VHC type spacer with facemask if <4 years old
Levalbuterol nebulizer soln. 0.31 mg/3 mL 0.63 mg/3 mL 2.5 mg/1 mL 1.25 mg/3 mL	Give at one-half the mg dose of albuterol above	Give at one-half the mg dose of albuterol above	The single isomer of albuterol is twice as potent on a mg basis
Levalbuterol MDI (45 mcg/puff)	See albuterol dose MOI dose	See albuterol dose MOI dose above	See albuterol MOI dose one-half as potent as albuterol on a microgram basis
Pirbuterol MDI (200 mcg/puff)	See albuterol MOI dose above		Has not been studied in acute severe asthma
Systemic β-agonists			
Epinephrine 1:1,000 (1 mg/mL)	0.3–0.5 mg every 20 min for 3 doses SQ	0.01 mg/kg up to 0.5 mg every 20 min for 3 doses SQ	No proven advantage of systemic therapy over aerosol
Terbutaline (1 mg/mL)	0.25 mg every 20 min for 3 doses SQ	0.01 mg/kg every 20 min for 3 doses, then every 2–6 h as needed SQ	Not recommended
Anticholinergics			
Ipratropium Br. nebulizer soln. (0.25 mg/mL)	500 mcg every 30 min for 3 doses, then every 2–4 h as needed	250 mcg every 20 min for 3 doses, then 250 mcg every 2–4 h	May mix in same nebulizer with albuterol; do not use as first-line therapy; only add to β_2-agonist therapy
Ipratropium Br. MDI (18 mcg/puff)	8 puffs every 20 min as needed for up to 3 h	4–8 puffs as needed every 2–4 h	
Corticosteroids			
Prednisone, methylprednisolone, prednisolone	40–80 mg in 1 or 2 divided doses until PEF reaches 70% of personal best	1 mg/kg (max. 60 mg/d) in 2 divided doses until PEF is 70% of normal predicted	For outpatient "burst" use 1–2 mg/kg/day, max. 60 mg, for 3–10 days in children and 40–60 mg/day in 1 or 2 divided doses for 5–10 days in adults

Note: No advantage has been found for very-high-dose corticosteroids in acute severe asthma, nor is there any advantage for intravenous administration over oral therapy. The usual regimen is to continue the oral corticosteroid for duration of hospitalization. The final duration of therapy following a hospitalization or emergency department visit may be from 3–10 days. If patients are then started on ICSs, there is no need to taper the systemic corticosteroid dose. ICSs can be started at any time during the exacerbation. *(From reference 2.)*

of prednisone, taught the purpose of the medications and proper inhaler technique, and referred to follow-up asthma care within 1 to 4 weeks; initiation of inhaled corticosteroids (ICSs) should also be considered.[2]

7 Early recognition of deterioration and aggressive treatment are the keys to successful treatment of acute asthma exacerbations. Thus patient and/or parent education teaching self-management skills and written action plans for early institution of therapy for acute exacerbations improve outcomes.[2] For more moderate to severe patients, this therapeutic plan also may include the availability of oral prednisone to begin at home.[2] Easy access by telephone to healthcare providers is also needed. Because of the rapid progression to severe asthma that can occur, patients and parents should be encouraged to communicate promptly with their asthma care provider during an exacerbation.

Figures 33–6 and 33–7 illustrate the recommended therapies for the treatment of acute asthma of mild, moderate, and severe exacerbations in home and emergency department/hospital settings, respectively.[2] The dosages of the drugs for acute severe exacerbations are provided in Table 33–6.[2,6] Institutions should strongly consider developing critical-pathways/treatment algorithms for their EDs because their implementation has been shown to improve outcomes and decrease the cost of care.[28] Finally, it is strongly recommended that an appointment with the patient's primary care provider be made within 1 week of the ED visit.[27]

NONPHARMACOLOGIC AND ANCILLARY THERAPY

Infants and young children may be mildly dehydrated owing to increased insensible loss, vomiting, and decreased intake.[2] Unless dehydration has occurred, increased fluid therapy is not indicated in acute asthma management because the capillary leak from cytokines and increased negative intrathoracic pressures may promote edema in the airways.[2] Correction of significant dehydration is always indicated, and the urine specific gravity may help to guide therapy in young children, in whom the state of hydration may be difficult to determine.[2] Chest physical therapy and mucolytics are not recommended in the therapy of acute asthma.[2] Sedatives should not be given because anxiety may be a sign of hypoxemia, which could be worsened by central nervous system depressants. Antibiotics also are not indicated routinely because viral respiratory tract infections are the primary cause of asthma exacerbations.[2] Antibiotics should be reserved for patients who

have signs and symptoms of pneumonia (e.g., fever, pulmonary consolidation, and purulent sputum from polymorphonuclear leukocytes). *Mycoplasma* and *Chlamydia* are infrequent causes of severe asthma exacerbations but should be considered in patients with high oxygen requirements.[2]

Respiratory failure or impending respiratory failure as measured by rising $Paco_2$ (≥45 mm Hg) or failure to correct hypoxemia with supplemental oxygen therapy is treated with intubation and mechanical ventilation.[27] In order to prevent barotrauma and pneumothoraces from excess positive pressure, it is recommended that controlled hypoventilation or permissive hypercapnia be used (correcting the hypoxemia, Pao_2 > 60 mm Hg, but allowing the $Paco_2$ to rise to the high 60 mm Hg range).[27]

PHARMACOTHERAPY

β_2-Agonists

4 The short-acting inhaled β_2-agonists are the most effective bronchodilators and the treatment of first choice for the management of acute severe asthma.[2,27] Up to 66% of adults presenting to an ED require only three doses of 2.5 mg nebulized albuterol to be discharged.[27] Most well-controlled clinical trials have demonstrated equal to greater efficacy and greater safety of aerosolized β_2-agonists over systemic administration regardless of the severity of obstruction.[2,27] Systemic adverse effects, hypokalemia, hyperglycemia, tachycardia, and cardiac dysrhythmias are more pronounced in patients receiving systemic β_2-agonist therapy. Children younger than 2 years of age achieve clinically significant responses from nebulized albuterol.[2,29] Effective doses of aerosolized β_2-agonists can be delivered successfully through mechanical ventilator circuits to infants, children, and adults in respiratory failure secondary to severe airways obstruction.[29]

Frequent administration of inhaled β_2-agonists (every 20 minutes or continuous nebulization) has been found to be superior to the same dosage administered at 1-hour intervals.[30] In the subset of more severely obstructed patients, continuous nebulization decreases the hospital admission rate, provides greater improvement in the FEV_1 and PEF, and reduces duration of hospitalization when compared with intermittent (hourly) nebulized albuterol in the same total dose.[30] Thus continuous nebulization is recommended for patients having an unsatisfactory response (achieving less than 50% of normal FEV_1 or PEF) following the initial three doses (every 20 minutes) of aerosolized β_2-agonists and potentially for patients presenting initially with PEF or FEV_1 values of less than 30% of predicted normal.[2,30]

The doses of inhaled β_2-agonists for acute severe asthma exacerbations (see Table 33–6) have been derived empirically. The β_2-agonists follow a log-linear dose-response curve.[31] In addition, the dose-response curve is shifted to the right by more severe bronchospasm or by increased concentrations of bronchospastic mediators, which is characteristic of functional antagonists.[31] The ability to increase the dose of the short-acting aerosolized β_2-agonists by as much as 5- to 10-fold over doses producing adequate bronchodilation in chronic stable asthma is what contributes to their efficacy in reversing the bronchospasm of acute severe exacerbations. The nebulizer dose of inhaled β_2-agonists for children often is listed on a weight basis (milligrams per kilogram). However, a fixed minimal dose (2.5 mg albuterol or equivalent), as opposed to a weight-adjusted dose, is more appropriate in younger children because children younger than 5 years of age receive a lower lung dose.[2] Adults dosed on a weight basis demonstrate excessive cardiac stimulation, so they have fixed maximal doses[2] (see Table 33–6). Initial doses of inhaled β_2-agonists can produce vasodilation, worsening ventilation-perfusion mismatch, slightly lowering oxygen saturation or Pao_2.[27] High-doses of inhaled β_2-agonists can produce a decrease in serum potassium concentration, an increase in heart rate, and an increase in serum glucose and lactic acid concentration.[31] However, both children and adults receiving continuously nebulized β_2-agonists have demonstrated decreased heart rates as their lung function improves.[30] Thus, an elevated heart rate is not an indication to use lower doses or to avoid using inhaled β_2-agonists.

Some controversy exists concerning the most cost-effective delivery system (MDI plus VHC vs nebulization) to be used in treating acute severe exacerbations in the ED and hospital (see below).[2,29] The DPIs are currently not indicated for the treatment of acute severe asthma exacerbations due to the higher inspiratory flows required for adequate drug delivery.[2,29]

Corticosteroids

Systemic corticosteroids are indicated in all patients with acute severe asthma exacerbations not responding completely to initial inhaled β_2-agonist administration (every 20 minutes for three to four doses).[2] Intravenous therapy offers no therapeutic advantage over oral administration.[2,32] This therapy usually is continued until hospital discharge. Tapering the systemic corticosteroid dose following discharge from the hospital appears unnecessary, provided that patients are prescribed inhaled corticosteroids for outpatient therapy.[2] Most patients achieve 70% of predicted normal FEV_1 within 48 hours and 80% of predicted by 6 days after plateauing by day 3. Thus, maintaining systemic corticosteroid courses for 10 to 14 days may be unnecessarily long in some patients. Indeed, many patients not admitted to the hospital respond to 3- to 5-day courses of systemic corticosteroids. Short courses of oral prednisone (3–10 day "bursts") have been effective in preventing hospitalizations in infants and young children.[2] It is recommended that a full dose of the corticosteroid be continued until the patient's peak flow reaches 70% of predicted normal or personal best.[2]

Multiple daily dosing of systemic corticosteroids for the initial therapy of acute asthma exacerbations appears warranted because receptor-binding affinities of lung corticosteroid receptors are decreased in the face of airways inflammation.[32] However, patients with less severe exacerbations may be treated adequately with once-daily administration. High-dose and very-high-pulse-dose corticosteroid regimens have not been shown to enhance the outcomes in severe acute asthma but are associated with a higher likelihood of side effects.[32]

Studies of ICSs in acute exacerbations of asthma have provided conflicting results. Studies have demonstrated both greater and lesser efficacy than standard doses of oral corticosteroids.[32] Currently, there is insufficient evidence supporting efficacy in the ED setting, although continued research appears warranted.[2] There is evidence that prescribing ICSs on discharge from the ED reduces the risk of relapse.[32] This policy is reasonable because inflammation is the underlying cause of deterioration in most cases.[2]

Anticholinergics

Inhaled ipratropium bromide produces a further improvement in lung function of 10% to 15% over inhaled β_2-agonists alone. In children and adults, multiple-dose ipratropium bromide added to initial therapy reduces hospitalization rate in the subset of patients with a baseline FEV_1 of less than 30% of predicted.[33] Ipratropium bromide, a quaternary amine, is poorly absorbed and produces minimal or no systemic effects. Care should be used when administering ipratropium bromide by nebulizer. If a tight mask or mouthpiece is not used, the ipratropium bromide that deposits in the eyes may produce pupillary dilatation and difficulty in accommodation. Ipratropium bromide is not a vasodilator, so unlike β_2-agonists it will not worsen ventilation-perfusion mismatch.[33]

Alternative Therapies

The ED use of aminophylline, a moderate bronchodilator, for acute asthma has not been recommended for a number of years.[2] Aminophylline in adults and children hospitalized with acute asthma does not enhance improvement in lung function or reduce length of hospitalization but has increased the risk of adverse effects.[34] Adverse effects of theophylline include nausea and vomiting and potentiation of the cardiac effects of the inhaled β_2-agonists.

Magnesium sulfate is a moderately potent bronchodilator, producing relaxation of smooth muscle and central nervous system depression.[35] The use of intravenous magnesium sulfate in patients presenting to the ED is controversial (see below).[35,36] The adverse effects of magnesium sulfate include hypotension, facial flushing, sweating, nausea, loss of deep tendon reflexes, and respiratory depression.[35] Helium is an inert gas of low density with no pharmacologic properties that can lower resistance to gas flow and increase ventilation because the low density decreases the pressure gradient needed to achieve a given level of turbulent flow, converting turbulent flow to laminar flow.[2] Helium is given as a mixture of helium and oxygen (heliox), usually 60% to 70% helium with 30% to 40% oxygen.[37] Heliox has been effective in some but not all clinical trials. Although heliox is free of adverse effects, its use is limited to patients with a low inspired oxygen requirement because the decrease in density generally is insignificant clinically with less than 60% helium.[37]

The inhalational anesthetics halothane, isoflurane, and enflurane all have been reported to have a positive effect in children and adults with acute severe asthma that is unresponsive to standard medical therapy.[2] The proposed mechanisms for inhalational anesthetics include direct action on bronchial smooth muscle, inhibition of airway reflexes, attenuation of histamine-induced bronchospasm, and interaction with β_2-adrenergic receptors.[2] Well-controlled trials with these agents have not been completed.[27] Potential adverse effects include myocardial depression, vasodilation, arrhythmias, and depression of mucociliary function.[27] In addition, the practical problem of delivery and scavenging these agents in the intensive care environment as opposed to the operating room is a concern. The use of volatile anesthetics cannot be recommended based on insufficient evidence of efficacy.

Ketamine has been recommended for rapid induction of anesthesia in patients with asthma who require intubation and mechanical ventilation.[2] Although anecdotal reports have suggested that ketamine is useful as a short-term adjunct in acute severe asthma; controlled trials have not provided evidence of efficacy. Ketamine has several significant adverse effects, including the anesthesia emergence reaction, which can alter mood and cause delirium. These emergence phenomena occur in at least 25% of patients over 16 years of age; the incidence seems to be much lower in younger patients.[2] Other risks include an increase in heart rate, arterial blood pressure, and cerebral blood flow because of its sympathetic effects.[27]

SPECIAL POPULATIONS

6 Infants and children younger than 4 years of age may be at greater risk of respiratory failure than older children and adults. Although treated with the same drugs, these younger children require the use of a facemask as opposed to a mouthpiece for delivery of aerosolized medication. Use of the facemask reduces delivery of drug to the lung by one-half so that a minimal dose is recommended as opposed to a weight-adjusted dose.[26,29] The facemask should be sized appropriately and should fit snugly over the nose and mouth. Use of the "blow by" method, where the respiratory therapist or parent places the mask or extension tubing near the child's nose and mouth, should be discouraged because holding the mask as few as 2 cm from the patient's face reduces lung delivery of the aerosol by 80%.[2,26]

DRUG CLASS INFORMATION

Short-Acting β_2-Agonists

5 6 The β_2-agonists are the most effective bronchodilators available. The β_2-adrenergic receptors are transmembrane proteins consisting of clusters of seven helices of amino acids that form the ligand-binding core.[31] The human β_2-adrenergic receptors are polymorphic in structure, with the most common polymorphisms in the amino terminus of the receptor at amino acid positions 16 (encoding either arginine [Arg] or glycine [Gly]) and 27 (encoding either glutamine [Gln] or glutamic acid [Glu]).[38] Some of the polymorphisms determine responsiveness to β_2-agonists, whereas others may act as disease modifiers (see below).[39] Stimulation of β_2-adrenergic receptor activates cytoplasmic G proteins, which in turn activate adenylyl cyclase to produce cyclic adenosine monophosphate (cAMP), generally thought to be responsible for the bulk of activity through activation of various proteins by cAMP-dependent protein kinase A (PKA).[31] This activation, in turn, decreases unbound intracellular calcium, producing smooth muscle relaxation, mast cell membrane stabilization, and skeletal muscle stimulation.[31] Despite the fact that β_2-agonists are potent inhibitors of mast cell degranulation in vitro, they do not inhibit the late asthmatic response to allergen challenge or the subsequent bronchial hyperresponsiveness.[2,31] Long-term administration of β_2-agonists does not reduce BHR, confirming a lack of significant antiinflammatory activity.[38] β_2-Adrenergic stimulation also activates Na^+-K^+-ATPase, produces gluconeogenesis, and enhances insulin secretion, resulting in a mild to moderate decrease in serum potassium concentration by driving potassium intracellularly.[31] The chronotropic response to β_2-agonists is mediated in part by baroreceptor reflex mechanisms as a result of the drop in blood pressure from vascular smooth muscle relaxation, as well as by direct stimulation of cardiac β_2-receptors and some β_1 stimulation at high concentrations.[31] Table 33–7 lists the pharmacologic effects of adrenergic receptor stimulation. Because β_1-receptor stimulation produces excessive cardiac stimulation, resulting in cardiac arrhythmias, and because the inotropic effect enhancing myocardial oxygen consumption leads to myocardial necrosis, there is no rationale for using non–β_2-selective agonists in the treatment of asthma.[31]

TABLE 33-7 Pharmacologic Responses to Sympathomimetic Agonists

Tissue	Receptor Type	Response
Airways	β_2	Smooth muscle relaxation (bronchodilation), increased ciliary beat, increased serous secretion, and inhibition of mast cell degranulation
	α	Smooth muscle contraction (bronchoconstriction?)
Heart	β_1	Inotropic and chronotropic
	β_2	Chronotropic
Vasculature	β_2	Vasodilation, decreased microvascular leakage
	α	Vasoconstriction
Skeletal	β_2	Increased neuromuscular transmission (tremor and increased strength of contraction)
Uterus	β_2	Relaxation (tocolysis)
Metabolic	α, β_1	Glycogenolysis, lipolysis
	β_2	Gluconeogenesis, hypokalemia, increased lactate production

TABLE 33-8 Relative Selectivity, Potency, and Duration of Action of the β-Adrenergic Agonists

	Selectivity			Duration of Action[b]		
Agent	β_1	β_2	***Potency, β_2***[a]	**Bronchodilation (h)**	***Protection (h)***[c]	***Oral Activity***
Isoproterenol	++++	++++	1	0.5–2	0.5–1	No
Albuterol	+	++++	2	4–8	2–4	Yes
Pirbuterol	+	++++	5	4–8	2–4	Yes
Terbutaline	+	++++	4	4–8	2–4	Yes
Formoterol	+	++++	0.12	≥12	6–12	Yes
Salmeterol	+	++++	0.5	≥12	6–12	No

[a]Relative molar potency to isoproterenol: 15 = lowest potency.
[b]Median durations with the highest value after a single dose and lowest after chronic administration.
[c]Protection refers to the prevention of bronchoconstriction induced by exercise or nonspecific bronchial challenges.

Table 33–8 compares the various β-adrenergic agonists used in asthma in terms of selectivity, potency, oral activity, and duration of action. The β_2-agonists are functional or physiologic antagonists in that they relax airway smooth muscle regardless of the mechanism for constriction.[31] When administered in equipotent doses, all the short-acting drugs produce the same intensity of response; the only differences are in duration of action and cardiac toxicity.[2,31] The catecholamine derivatives all have the disadvantage of rapid inactivation of their 3,4-hydroxyl catechol group from catechol-O-methyltransferase found in the gastrointestinal tract, rendering them orally inactive. In addition, catecholamines are taken up rapidly into tissues by secondary uptake mechanisms that limit their receptor occupancy and thus have a shorter duration of action.[31] All the β_2-agonists are more bronchoselective when administered by the aerosol route. Aerosol administration of the short-acting β_2-agonists provides more rapid response and greater protection against provocations that induce bronchospasm such as exercise and allergen challenges than does systemic administration.[2,31] Differences in myocardial effects are discernible between selective and nonselective agents even when administered as aerosols, particularly at the higher doses used for acute severe asthma. The β_2-agonists also differ in efficacy or ability to activate the β_2-adrenergic receptors. Full agonists include the catecholamines while the synthetic β_2-agonists all exhibit various levels of partial agonism in the following order of fuller agonism: formoterol > albuterol = terbutaline = pirbuterol > salmeterol.[31] Although partial agonists by definition cannot produce maximum dilation or protection as full agonists and can potentially block the effect of a full agonist, these differences have not been proven to be clinically significant.

All synthetic β_2-agonists are 1:1 racemic mixtures of two mirror images (enantiomers) owing to an asymmetric or chiral carbon.[31] Since most physiologic functions (receptor occupancy and activation and enzymatic metabolism) are stereoselective, the (*R*)-enantiomers of the β_2-agonists are the most pharmacologically active isomer.[31] While it was felt initially that the (*S*)-enantiomers were essentially inactive owing to the 100 to 1,000-fold potency difference between the enantiomers, studies in animal models and isolated in vitro tissue preparations have suggested that the (*S*)-enantiomer of albuterol may be proinflammatory and could induce BHR.[31] However, evidence that this occurs consistently in humans or is clinically relevant is lacking (see below).[31] The pharmacokinetics are stereoselective as well, although not predictable. (*R*)-Albuterol is metabolized more rapidly than (*S*)-albuterol, which could lead to accumulation of (*S*)-albuterol with continued dosing.[31] On the other hand, (*S*)-terbutaline is eliminated more rapidly than (*R*)-terbutaline.[38]

Both the intensity and duration of response are dose dependent, and more important, the dose-response relationship is dynamic.[31] At increasing levels of baseline bronchoconstriction (irrespective of the stimulus), the dose-response curve is shifted to the right, and the duration of bronchodilation is decreased.[31] This shift is reflected in the need for higher, more frequent doses in acute asthma exacerbations; the duration of protection against significant provocation is much less than the duration of bronchodilation in chronic stable asthma (see Table 33–8).[31,38]

Chronic administration of β_2-agonists leads to downregulation (decreased number of β_2-receptors) and a decreased binding affinity (desensitization) for these receptors.[31] Systemic corticosteroid therapy can both prevent and partially reverse this phenomenon.[2,31] However, the use of inhaled corticosteroids appears to have minimal ability to prevent tolerance to β_2-agonists.[31] Although in vitro differences in downregulation of the β_2-receptors exist (Gly-16 homozygotes > Arg-16 homozygotes), clinical desensitization is seen in all polymorphisms.[38] Tolerance primarily reduces duration of bronchodilation as opposed to peak response, although that can occur as well. A significantly greater tolerance develops in other tissues (e.g., lymphocytes and cardiac and skeletal muscle) compared with the lung, primarily as a result of the surplus β_2-receptors found in respiratory smooth muscle.[31] Tolerance to the extrapulmonary effects (cardiac stimulation and hypokalemia) may account for a lack of significant cardiac effects with retention of the bronchodilator response despite chronic inhaled β_2-agonist therapy, whereas tolerance to mast cell stabilization may be a drawback to chronic use.[31] Thus, chronic β_2-agonist administration produces a tolerance of minimal clinical significance that is overcome easily by increasing the dose or by administering corticosteroids.[2,31,38] Most of the tolerance occurs within a week of regular administration and does not worsen with continued administration. As would be expected from a receptor phenomenon, tolerance is a cross-tolerance to all β_2-agonists.[31] Whether or not regular use of short-acting inhaled β_2-agonists produces worsening of asthma in a subset of patients remains controversial (see below), but it does not appear to occur in the entire population.[38] Regular treatment with short-acting β_2-agonists can increase BHR and in homozygous Arg-16 patients reduces morning PEF and increases exacerbations.[39] Regular treatment (4 times daily) does not improve symptom control over as-needed use and is not indicated.[2]

In conclusion, the short-acting inhaled selective β_2-agonists are indicated for the as needed treatment of intermittent episodes of bronchospasm. They are the first treatment of choice for acute severe asthma and exercise-induced bronchospasm.[2,31] They inhibit EIB in a dose-dependent fashion and provide complete protection for a 2-hour period following inhalation with varying levels of patient-dependent protection over 4 hours.[31] Although the regular administration of β_2-agonists slightly decreases the effect, two inhalations prior to exercise still

TABLE 33-9 Pharmacodynamic/Pharmacokinetic Comparison of the Corticosteroids

Systemic	Antiinflammatory potency	Mineralcorticoid potency	Duration of biologic activity (h)	Elimination half-life (h)
Hydrocortisone	1	1.0	8–12	1.5–2.0
Prednisone	4	0.8	12–36	2.5–3.5
Methylprednisolone	5	0.5	12–36	3.3

FLU	1.8	20	58	1.6/1.6
FP	18	≤1	66	7.8/14.4
MF	23[b]	<1	53	5.8/UK
TAA	3.6	23	45–69	2.0/3.6

Note: Receptor binding affinities are relative to dexamethasone equal to 1. UK = unknown.
[a]BDP and CIC are prodrugs that are activated in the lung to their active metabolites BMP and des-CIC, respectively.
[b]MF studied in a different receptor system. Value estimated from relative values of BDP, TAA, and FP in that system.
BUD, budesonide; CIC, ciclesonide; des-CIC, des-ciclesonide; FLU, flunisolide; FP, fluticasone propionate; MF, mometasone furoate; TAA, triamcinolone acetonide; BDP, beclomethasone dipropionate; BMP, beclomethasone 17-monopropionate.

essentially blocks exercise-induced bronchospasm completely (1% vs 5% drop in FEV_1).[31]

Systemic Corticosteroids

4 The corticosteroids are the most effective antiinflammatories available to treat asthma.[2] Actions useful in treating asthma include (1) increasing the number of β_2-adrenergic receptors and improving the receptor responsiveness to β_2-adrenergic stimulation, (2) reducing mucus production and hypersecretion, (3) reducing BHR, and (4) reducing airway edema and exudation.[2,40] The glucocorticoid receptor is found in the cytoplasm of most body cells, explaining the multiple effects of systemic corticosteroids. There is no difference between glucocorticoid receptors found throughout the body; however, genetic differences between glucocorticoid receptors from different individuals may determine some of the variations in response.[39] The corticosteroids are lipophilic, readily cross the cell membrane, and combine with the glucocorticoid receptor. The activated complex then enters the nucleus, where it acts as a transcription factor leading to gene activation or suppression.[40] This leads to specific mRNA production, resulting in increased production of antiinflammatory mediators; supression of several proinflammatory cytokines such as IL-1, GM-CSF, IL-4, IL-5, IL-6, and IL-8, reducing inflammatory cell activation, recruitment, and infiltration; and decreasing vascular permeability.[40] In addition, the activated glucocorticoid receptor complex can act directly with cytoplasmic transcription factors, nuclear factor κB, and activating protein 1 to prevent the action of proinflammatory cytokines on the cell.[40]

Owing to the mechanism that modifies gene expression, the time required to see the particular effect depends on the time required for new protein synthesis, decreased formation of the particular mediator, and resolution of the inflammatory response.[40] Generally, the cellular and biochemical effects are immediate, but varying amounts of time are required to produce a clinical response. β_2-Receptor density increases within 4 hours of corticosteroid administration.[40] Improved responsiveness to β_2-agonists occurs within 2 hours.[40] In acute severe asthma, 4 to 12 hours may be required before any clinical response is noted.[32,40] Reversal of seasonally increased BHR requires at least 1 week of therapy.[40] The chronic use of corticosteroids does not induce a state of corticosteroid dependence. Nor is there evidence of tolerance produced by chronic administration.

The corticosteroids used in asthma are compared in Table 33–9.[40,41] Besides acute severe asthma, systemic corticosteroids are also recommended for the treatment of impending episodes of severe asthma unresponsive to bronchodilator therapy.[2,32] The effects of corticosteroids in asthma are dose and duration dependent. This pattern is true for the adverse effects as well (Table 33–10). The clinician must continually balance the toxicity of chronic systemic corticosteroid therapy with control of asthma symptoms. Because short-term (1–2 weeks) high-dose corticosteroids (1–2 mg/kg per day of prednisone) do not produce serious toxicities, the ideal use is to administer the systemic corticosteroids in a short "burst" and then to maintain the patient on appropriate long-term control therapy with ICSs (discussed below).[2,32] In general, therapy for more than 5 days at doses that exceed the usual physiologic endogenous cortisol production will cause temporary aberration in adrenal cortisol release.[40] However, this hypothalamic-pituitary-adrenal (HPA) axis suppression is short-lived (1–3 days) and readily reversible following short bursts (≤10 days) of pharmacologic doses.[40] A maximum number of short bursts that a patient can receive probably exists, after which chronic corticosteroid side effects occur. Adult patients receiving at least eight bursts (≥10 days each) have a similar decrease in trabecular bone density as patients on daily or alternate-day corticosteroids over 1 year.[40] Children who received four or more bursts of prednisone exhibited a subnormal response to hypoglycemic stress or adrenocorticotropic hormone (ACTH) administration and two or more bursts/year increase the risk for osteopenia in

TABLE 33-10 Adverse Effects of Chronic Systemic Glucocorticoid Administration

Hypothalamic–pituitary-adrenal suppression	Hypertension
Growth retardation	Skin striae
Skeletal muscle myopathy	Impaired wound healing
Osteoporosis/fractures	Inhibition of leukocyte and monocyte function
Aseptic necrosis of bone	Subcutaneous tissue atrophy
Pancreatitis	Glaucoma
Pseudotumor cerebri	Posterior subcapsular cataracts
Psychiatric disturbances	Moon facies
Sodium and water retention	Central redistribution of fat
Hypokalemia/hyperglycemia	

children.[40,42] Very short courses (3–5 days) have been effective in reducing hospitalization from acute exacerbations.[2] Use of the shorter-acting corticosteroids such as prednisone will produce less adrenal suppression than the longer-acting dexamethasone.[40]

Anticholinergics

The anticholinergic agents have a long history of use for asthma, but they do not have a FDA labeled indication for asthma.[2] Anticholinergics are competitive inhibitors of muscarinic receptors.[43] Unlike β_2-agonists, they are not functional antagonists; they only reverse cholinergic-mediated bronchoconstriction. Normal bronchial tone is maintained through parasympathetic innervation of the airways via the vagus nerve.[40] A number of the triggers and mediators of asthma (i.e., histamine, prostaglandins, sulfur dioxide, exercise, and allergens) produce bronchoconstriction in part through vagal reflex mechanisms.[40] Studies consistently demonstrate that anticholinergics are effective bronchodilators in asthma, although not as effective as β_2-agonists. Anticholinergics attenuate but do not block allergen-induced asthma in a dose-dependent fashion and have no effect on BHR.[43] Anticholinergics attenuate but do not block EIB.[44]

Ipratropium bromide is a nonselective muscarinic receptor blocker, and blockade of inhibitory muscarinic receptors theoretically could result in an increased release of acetylcholine and overcome the block on the smooth muscle receptors (M_3).[43] Only the quaternary ammonium derivatives such as ipratropium bromide should be used because they have the advantage of poor absorption across mucosae and the blood–brain barrier. This attribute contributes to negligible systemic effects with a prolonged local effect (i.e., bronchodilation). In addition, the quaternary compounds do not appear to produce a decrease in mucociliary clearance.[43] Ipratropium bromide has a duration of action of 4 to 8 hours. Both intensity and duration of action are dose dependent. Tiotropium bromide, a long-acting inhaled anticholinergic with duration of 24 hours, is more selective for M_1 and M_3 receptors and less likely to affect the inhibitory M_2 receptors.[43] Time to reach maximum bronchodilation for ipratropium is considerably slower than from aerosolized short-acting β_2-agonists (30–60 minutes vs 5–10 minutes). However, this difference is of little clinical consequence because some bronchodilation is seen within 30 seconds; 50% of maximum response occurs within 3 minutes.[43] Ipratropium bromide is only indicated as adjunctive therapy in acute severe asthma not completely responsive to β_2-agonists alone because it does not improve outcomes in chronic asthma.[2,33] Tiotropium studies in chronic asthma are ongoing.

PHARMACOECONOMICS

Emergency department visits for asthma exceed the number of hospitalizations by approximately 4 times, yet the annual expenditures for ED visits remain significantly less than that spent on in-patient hospital services for patients with acute severe asthma.[3,27] Thus, reducing the number of patients requiring hospitalizations is a primary goal of therapy. Since the primary drugs used to treat acute severe asthma are available generically, drug costs account for only a small portion of the overall costs of care. Few of these therapies have been evaluated formally for their pharmacoeconomic impact. One evaluation based on a meta-analysis of inhaled anticholinergics added to short-acting inhaled β_2-agonists in children with acute severe asthma suggested that this approach was cost-effective and would reduce overall costs by reducing hospitalizations.[26,29] In children with acute severe asthma admitted to an intensive care unit, the use of continuously nebulized albuterol resulted in a decreased cost of care compared with intermittent nebulization.[26]

CLINICAL CONTROVERSIES

Some clinicians believe that intravenous magnesium sulfate is effective for the treatment of acute severe asthma exacerbations unresponsive to standard doses of inhaled β_2-agonists in the ED. This belief is based on subset analyses of two studies showing that patients with the most severe obstruction following initial inhaled β_2-agonists demonstrated a reduction in hospitalizations with magnesium treatment compared with placebo.[35] However, the subset with severe obstruction is the one demonstrating an improved response to the addition of ipratropium bromide and continuous nebulization of inhaled β_2-agonists. In addition, a large, randomized trial failed to confirm a decrease in hospitalization even in the severe group.[36] The 2007 NAEPP guidelines state that magnesium can be considered for use in patients with severe episodes with a poor response to initial inhaled β_2-agonists.[2]

Numerous studies have shown that the inhaled β_2-agonists administered by MDI plus VHC provide a similar outcome in acute severe asthma as drug administration by jet nebulizers.[29] Proponents of administration by MDI plus VHC argue that it is more cost-effective and so should replace nebulizer therapy. However, appropriate cost analyses have yet to be performed.[26] Comparisons in the most severe subsets with combination therapy and continuous nebulization have not been done.[2,26] Current practice should be based on the comfort level of the clinical staff until sufficient data are available to warrant a wholesale recommendation of one method.[2]

EVALUATION OF THERAPEUTIC OUTCOMES

Figures 33–6 and 33–7 provide the monitoring parameters for acute severe asthma. Lung function, either spirometric or peak flow measurements, should be monitored 5 to 10 minutes after each treatment.[2] Oxygen saturations can be easily monitored continuously with pulse oximetry. For young children and infants, pulse oximetry, lung auscultation, and observation of the presence of supraclavicular retractions are useful.[2,27] The majority of patients will respond within the first hour of initial inhaled β_2-agonists regardless of history of home administration of drug.[27] Patients not achieving an initial response should be monitored every half hour to 1 hour. Depending on whether there is a standard ED or a special unit for acute severe asthma, the decision to admit to the hospital should be made within 4 to 6 hours of entry to the emergency department.[27] The mean duration of hospitalization following admission is 2 to 3 days. Frequency of monitoring depends on the severity of the exacerbation. With mild exacerbations, monitor lung function every 2 to 3 hours and severe exacerbations every half hour to 1 hour.

TREATMENT

Chronic Asthma

The diagnosis of chronic asthma is made primarily by history and confirmatory spirometry (see Clinical Presentation above).[2] The NAEPP has provided a list of questions that would lead to the diagnosis of asthma[2] (see Table 33–2). In the older child and adult patient in whom spirometric evaluations can be performed, failure of pulmonary functions to improve acutely does not necessarily rule out asthma. Patients with long-standing disease or substantial inflammation may require an intensive, prolonged

course of bronchodilators and glucocorticoids before reversibility is detected.[2] If baseline spirometry is normal, challenge testing with exercise, histamine, methacholine, or mannitol can be used to elicit BHR.[2] Patients with significant symptoms and/or an FEV_1 of less than 70% of predicted normal should not be challenged. Vocal cord dysfunction, particularly with exercise, may mimic asthma symptoms.[2] Studies for atopy such as serum IgE and sputum and blood eosinophil determinations are not necessary to make the diagnosis of asthma, but they may help differentiate asthma from chronic bronchitis in adults. Clinically, this distinction is often difficult to make. Some patients with chronic bronchitis may have a reversible component, and some patients with long-standing severe chronic asthma may have significant irreversible damage and obstruction. Very high peripheral blood eosinophil counts may point to the diagnosis of allergic bronchopulmonary aspergillosis (ABPA) or other hypereosinophilic syndromes.[2] Skin testing is of no value in diagnosing asthma but is useful in identifying triggers.[2] In small infants unable to perform spirometry, the diagnosis is more difficult. Hyperinflation may be demonstrated on the chest roentgenogram.[2] Radiologic examination is helpful in ruling out other causes of wheezing (e.g., foreign-body aspiration, parenchymal lung disease, cardiac disease, and congenital anomalies).[2] In place of pulmonary function measures, the parents should be given a diary card to record symptoms and precipitating events.

GOALS FOR MANAGING ASTHMA LONG-TERM

The NAEPP has provided key points for managing asthma long term.[2] The goal for therapy is to control asthma by:

Reducing impairment

1. Prevent chronic and troublesome symptoms (e.g. coughing or breathlessness in the daytime, in the night, or after exertion)
2. Require infrequent use (≤2 days a week) of short-acting inhaled β_2-agonist for quick relief of symptoms[2] (not including prevention of EIB)
3. Maintain (near) normal pulmonary function
4. Maintain normal activity levels (including exercise and other physical activity and attendance at work or school)
5. Meet patients' and families' expectations of and satisfaction with asthma care

Reducing risk

1. Prevent recurrent exacerbations of asthma and minimize the need for ED visits or hospitalizations
2. Prevent loss of lung function; for children, prevent reduced lung growth
3. Minimal or no adverse effects of therapy

NONPHARMACOLOGIC THERAPY

Although the mainstay of the management of asthma is pharmacologic therapy, it is likely to fail without concurrent attention to relevant environmental control and management of comorbid conditions. Figure 33–8 depicts the stepwise approach for managing asthma recommended in the newest update by the NAEPP.[2] Nonpharmacologic aspects of therapy are incorporated into the steps. The guidelines were designed to give primary healthcare providers a framework with which to develop the proper approach to the individualized therapy of patients. The heterogeneity of asthma demands an individualized approach to therapy with the basic goals of therapy as primary outcome measures.[2] The focus of therapy is the prevention and suppression of the underlying inflammation.[2] Thus current therapeutic options in asthma consist of acute reliever medications used for acute symptoms and exacerbations and long-term control medications used for the prevention

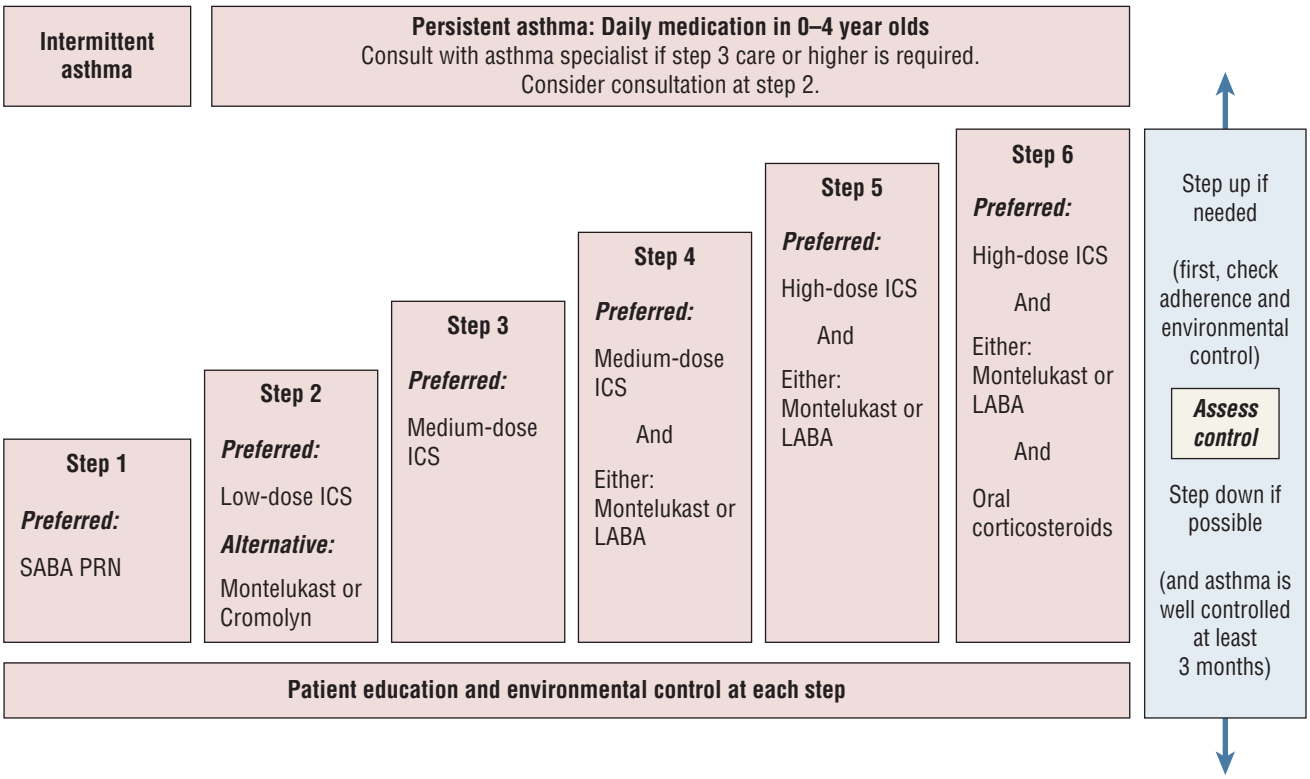

FIGURE 33-8. Stepwise approach for managing asthma in adults and children 0 to 4 years old and 5 to 11 years old. *(From reference 2.)*

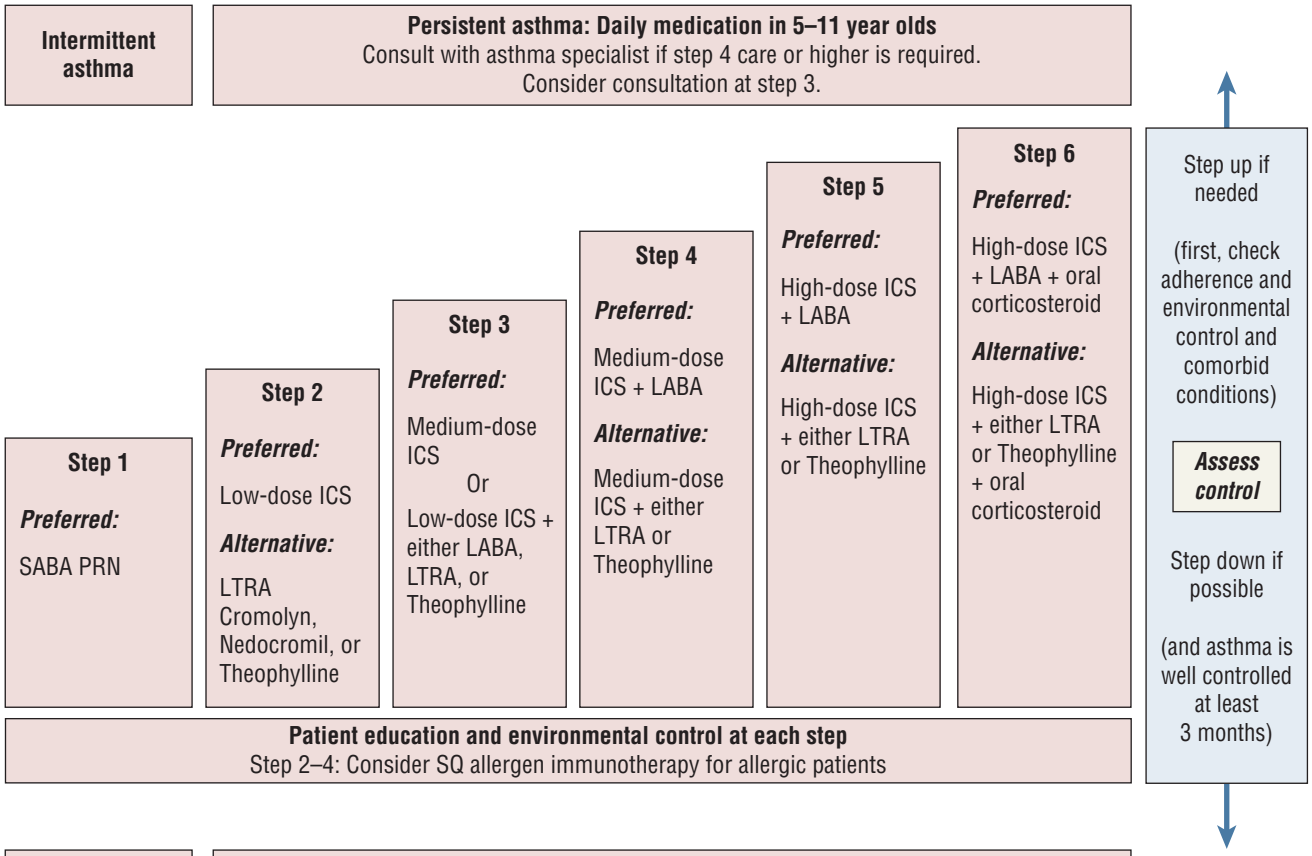

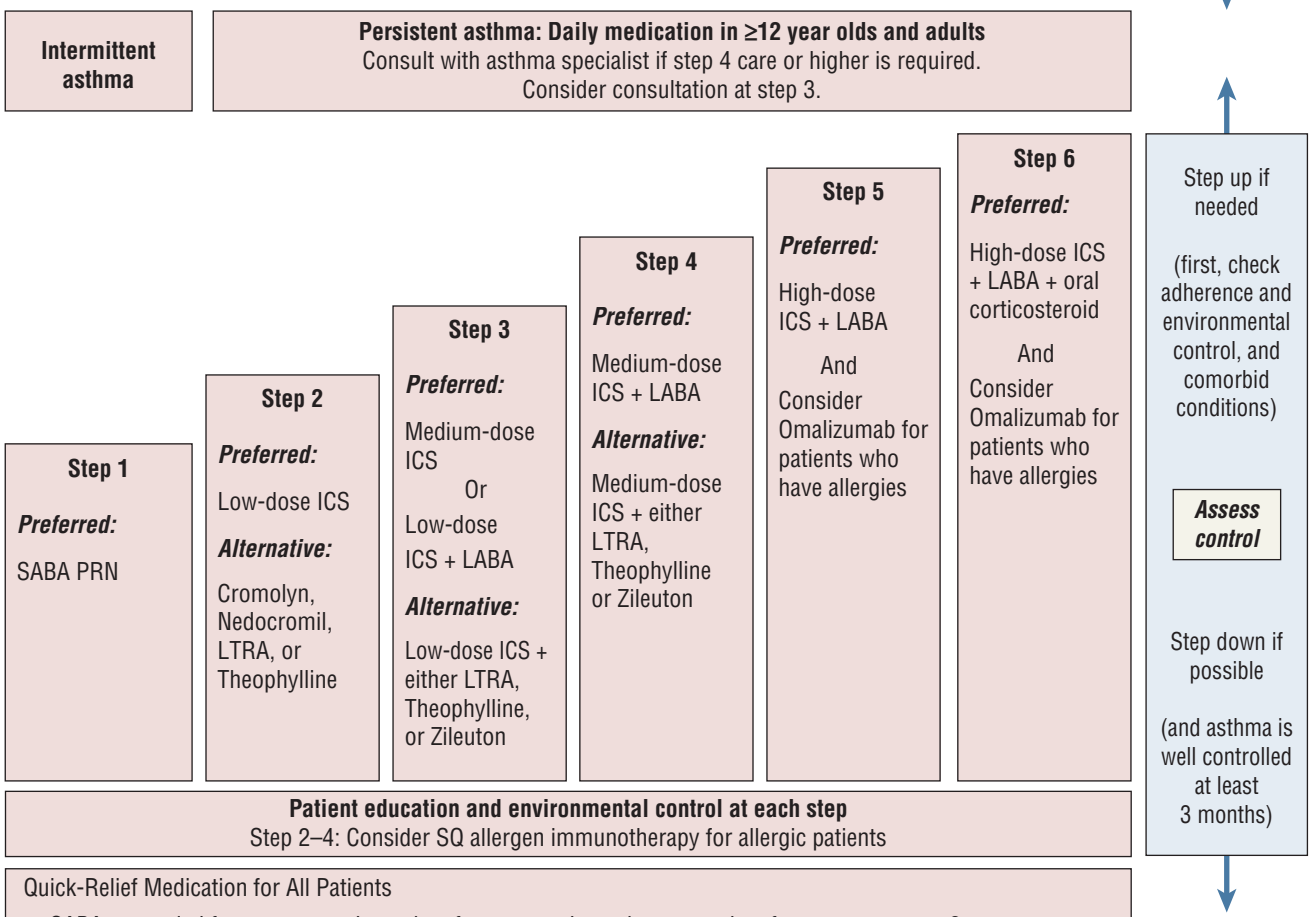

Quick-Relief Medication for All Patients

- SABA as needed for symptoms. Intensity of treatment depends on severity of symptoms: up to 3 treatments at 20-minute intervals as needed. Short course of systemic oral corticosteroids may be needed.
- Use of beta2-agonist >2 days a week for symptom control (not prevention of EIB) indicates inadequate control and the need to step up treatment.

FIGURE 33-8. *(continued)*

TABLE 33-11 Key Educational Messages for Patients

Basic facts about asthma
- The contrast between asthmatic and normal airways
- What happens to the airways in an asthma attack

Roles of medications
- How medications work
- Long-term control: medications that prevent symptoms, often by reducing inflammation
- Quick relief: short-acting bronchodilator relaxes muscles around airways
- Stress importance of long-term-control medications and not to expect quick relief from them

Skills
- Inhaler use (patient demonstrate)
- Spacer and holding chamber use
- Use of the nebulizer
- Symptom monitoring, peak flow monitoring, and recognizing early signs of deterioration
- How to assess asthma control after therapy has begun

Environmental control measures
- Identifying and avoiding environmental precipitants or exposures, including tobacco smoke

When and how to adjust treatment
- Using written action plan
- Responding to changes in asthma control

of symptoms and exacerbations and the suppression of inflammation and reduction of BHR.[2]

7 The development of a partnership in care through patient education and the teaching of patient self-management skills should be the cornerstone of any treatment program.[2] There are a number of published self-management programs for children and adults available through local American Lung Association chapters, as well as asthma treatment centers, and nationally through the NAEPP and the Asthma and Allergy Foundation of America.[2] Asthma self-management programs have been shown to improve patient adherence to medication regimens, improve self-management skills, and improve use of healthcare services.[2,46,47] Table 33–11 lists the key educational messages recommended by the NAEPP.[2]

Self-management programs instruct patients in the pathogenesis of asthma and the appropriate use of their medications but focus principally on teaching patients to recognize triggers for their asthma and how to recognize early signs of deterioration.[46] Home PEF monitoring is part of some programs.[2] However, routine PEF monitoring in and of itself does not improve patient outcomes.[2]

The NAEPP advocates the use of PEF monitoring only for patients with severe persistent asthma who have difficulty perceiving airway obstruction.[2] The NAEPP also has recommended a system based on a traffic light scenario (based on percentage of normal predicted values or personal best values): The green zone is equal to 80% to 100%, the yellow zone is equal to 50% to 79%, and the red zone is less than 50%. The yellow zone is cautionary and requires increasing as-needed bronchodilator use and possibly beginning prednisone if not improved, whereas the red zone warrants contacting the patient's healthcare provider.[2]

Patient education is essential before monitoring can be effective. Patient education has proved successful regardless of the health professional who provided the information (physician, nurse, or pharmacist). The NAEPP advocates significant involvement of all points of patient care in the educational process.[2] The provision of written action plans enhances the success of education and is considered an essential component of care.[2] Samples of clinically tested written action plans are available from NAEPP guidelines and other sources.[2]

In patients with known allergic triggers for their asthma, allergen avoidance has resulted in an improvement in symptoms, a reduction in medication use, and a decrease in BHR.[2] A comprehensive approach to environmental control is advocated. For example, for patients with house dust mite allergy removing carpeting from bedrooms, washing sheets in hot water (>130°F), and using special dust-proof pillow and mattress covers can reduce symptoms and need for medications.[2] Obvious environmental triggers (e.g., animal dander, cockroaches), if the patient is sensitive, should be avoided. Evidence for home air-filtering systems and chemicals for killing house dust mites is limited.[2] Immunotherapy (allergy shots) with single antigens particularly, has been beneficial and may be considered in patients with persistent asthma with documented sensitivity.[2] Immunotherapy with multiple antigens has been less effective.

Patients who smoke should be encouraged to stop. Parents of children with asthma should stop or at least not smoke around their children.[2]

PHARMACOLOGIC THERAPY

The current NAEPP recommendations for therapy of persistent asthma are illustrated in Figure 33–8.[2] Therapy should be adjusted based on control status of the patient (refer to later section). Regardless of the long-term therapy, all patients need to have quick-relief medication in the form of short-acting inhaled β_2-agonists available for acute symptoms. The ICSs are considered the preferred long-term control therapy for persistent asthma in all patients due to their potency and consistent effectiveness.[2] Low- to medium-dose ICSs reduce BHR, improve lung function, and reduce severe exacerbations leading to emergency department visits and hospitalizations. They are more effective than cromolyn, theophylline, or the leukotriene receptor antagonists.[2] In addition, the ICSs are the only therapy that reduces the risk of dying from asthma.[48] In the low to medium doses recommended by NAEPP guidelines (Table 33–12), ICSs are safe for long-term administration (see below).[2,41] The ICSs do not appear to reduce airway remodeling and loss of lung function found in some patients with persistent asthma. The ICSs do not enhance lung growth in children with asthma, prevent the development of asthma in high risk infants, nor do they induce remission of asthma as BHR and other measures of inflammation return to pretreatment levels upon discontinuation of therapy.[49,50] The sensitivity and consequent clinical response to ICSs can vary among patients.[2]

Although studies of the alternative long-term control therapies (e.g., cromolyn, leukotriene receptor antagonists, and theophylline) demonstrate improvement in symptoms, lung function, and as-needed, short-acting inhaled β_2-agonist use, they do not reduce BHR, suggesting minimal antiinflammatory activity.[2] The evidence suggests minimal to no differences in efficacy between these alternatives. Therefore, NAEPP lists them in alphabetical order to show no preference of one over the other.[2]

For those patients inadequately controlled on low dose ICSs either an increased dose of the ICS or the combination of ICS and long-acting inhaled β_2-agonist (LABA) is the next step to gain control of more moderate persistent asthma.[2] Alternatives could be the addition of leukotriene modifiers or theophylline to ICSs.[2] The addition of theophylline or leukotriene modifiers to ICSs is no more effective than doubling the dose of the ICS.[2] The combination of ICS/LABA is more effective at reducing severe asthma exacerbations than doubling the dose of ICS in moderate persistent asthma; increasing the dose of ICSs 4-fold also will result in a significant reduction in exacerbations.[51,52] However, doses of ICSs in the high range significantly enhance the risk of toxicity.[41,49] Thus, high doses of ICSs plus LABA are reserved for patients with severe persistent asthma.[2]

TABLE 33-12 Available Inhaled Corticosteroid Products, Lung Delivery, and Comparative Daily Dosages

ICS	Product	Lung Delivery[a]
Beclomethasone dipropionate (BDP)	40 and 80 mcg/actuation HFA MDI, 120 actuations	55%–60%
Budesonide (BUD)	90 or 180 mcg/dose DPI, Flexhaler, 200 doses	32% (15–30%)
	200 and 500 mcg ampules, 2 mL each	5%–8%
Ciclesonide (CIC)	80 or 160 mcg/actuation HFA MDI	50%
Flunisolide (FLU)	250 mcg/actuation CFC MDI, 100 actuations	20%
	80 mcg/actuation HFA MDI, 120 actuations	68%
Fluticasone propionate (FP)	44, 110, and 220 mcg/actuation HFA MDI, 120 actuations	20%
	50, 100 and 250 mcg/dose DPI, Diskus, 60 doses	15%
Mometasone furoate (MF)	110 and 220 mcg/dose DPI, Twisthaler, 14, 30, 60, and 120 doses	11%
	Comparative Daily Dosages (mcg) of Inhaled Corticosteroids

[a]5 to 11 years of age, except for BUD Nebules which is 2 to 11 years of age.

Although the addition of a third controller medication is often used clinically in patients with severe persistent asthma uncontrolled on high dose ICS/LABA, there are few studies evaluating this practice.[2] Leukotriene receptor antagonists or theophylline added to high-dose combination ICS/LABA do not improve outcomes.[2] Omalizumab, a recombinant anti-IgE has demonstrated significant activity in these severe uncontrolled atopic patients.[2,53]

SPECIAL POPULATIONS

6 Children younger than 5 years of age have not been studied adequately. Thus, many of the recommendations in this age group are extrapolated from older children and adults.[2] The studies of ICSs in this younger group demonstrate improvement in symptoms, as needed bronchodilator use, and exacerbations. The nebulized suspension of budesonide gained FDA approval from three pivotal efficacy and safety trials.[2] The FDA approval for montelukast in children younger than age 6 was based on safety and pharmacokinetic studies establishing doses but not on efficacy although improvement in symptoms and as needed bronchodilators was noted.[2] Cromolyn nebulizer solution was approved down to age 2 years based on efficacy.[2] Theophylline has not been evaluated adequately, except for pharmacokinetics.[2] Combination therapy of any kind has not been studied except for a small number of patients down to 4 years of age on ICS/LABA.[2]

The FDA approval of the fluticasone/salmeterol DPI 100/50 in patients 4 to 11 years of age was largely based on extrapolation of efficacy data from patients older than 12 years of age and by a single safety and efficacy study in children with asthma aged 4 to 11 years. In children 5 to 11 years old, the ICS/LABA combination has not yet been definitively shown to decrease exacerbations compared with medium dose ICS, although impairment domains improved.[2] The only study of the addition of montelukast to ICS showed minimal improvement in PEF and as needed albuterol use.[2] Thus, combination therapy has been inadequately studied to date in this population.

Owing to the increased risk of osteoporosis and cataracts in the elderly, patients requiring high doses of ICSs should have routine bone mineral density determinations and ophthalmic exams.[2,54] Appropriate therapies for prevention of osteoporosis should be instituted.[2,54]

Asthma affects 7% of pregnant women, making it potentially the most common serious medical condition to complicate pregnancy.[19] Maternal asthma has been reported to increase the risk of perinatal mortality, preeclampsia, preterm birth, and low-birthweight infants.[19] More severe asthma is associated with increased risks, whereas better-controlled asthma is associated with decreased risks. A systematic review of the evidence on the safety of asthma medications has concluded that it is safer for pregnant women with asthma to be treated with effective medications than for them to have exacerbations.[19] Proper monitoring and control of asthma should enable a woman with asthma to maintain a normal pregnancy with little or no risk to mother or her fetus.

A stepwise approach to managing asthma during pregnancy and lactation has been published, with low-dose ICSs recommended as preferred treatment for mild persistent asthma with the addition of a LABA if not adequately controlled.[19] Budesonide is considered the preferred ICS to initiate because it has the greatest amount of safety data.[19] Albuterol is considered the preferred rescue therapy.[19]

DRUG CLASS INFORMATION

Inhaled Corticosteroids

The mechanism of action of the corticosteroids has been reviewed (see above). The principal advantage of the ICSs is their high topical potency to reduce inflammation in the lung and low systemic activity.[41,49] The ICSs have high antiinflammatory potency, approximately 1,000-fold greater than endogenous cortisol, and differ from each other by as much as 4- to 6-fold.[41] However, potency differences, which are simply a measure of binding affinity to the

receptor, can be overcome simply by giving different microgram dosages of drug. Aerosol delivery of the preparations is remarkably variable, ranging from 10% to 60% of the nominal dose (i.e., that dose which leaves an actuator for an MDI or, in the case of a DPI, that which is released on actuation of the inhaler).[26,41] Different devices for the same chemical entity may result in 2-fold differences in delivery, so that delivery method can make a significant difference in the relative comparable dose or therapeutic index.[2,41]

The ICSs, beclomethasone dipropionate, budesonide, ciclesonide, flunisolide, fluticasone propionate, and mometasone furoate, that are currently available for use are compared and listed in Table 33–12. The ICSs have pharmacokinetic differences that result in different topical/systemic activity.[41] Most evidence is consistent with log-linear dose-response curves for both indirect and direct responses.[49] The log-linear nature of the dose-response curve for ICS activity raises the issue of how much of a difference in dose (or lung delivery) or potency is detectable. The measures used to assess efficacy (lung function, BHR, symptoms, and as-needed short-acting inhaled β_2-agonist use) are downstream events from the antiinflammatory activity.[49] It takes a 4-fold difference in potency or dose to detect clinically significant differences in efficacy. The table of comparable ICS doses (see Table 33–12) is based on extensive clinical trial data.[2,41] Clinically comparable doses take into consideration drug potency differences as well as device delivery differences but not the potential for systemic activity.

Since the glucocorticoid receptors within the various tissues are the same, differences in the pharmacokinetic profile are required to produce differences in the topical/systemic effect ratio (therapeutic index).[41] Pharmacokinetic properties that enhance topical selectivity include rapid systemic clearance, poor oral bioavailability, and prolonged residence time in the lung.[41] Owing to their high lipophilicity, systemic clearance of the available ICSs is very rapid, approaching the rate of liver blood flow with the exception of ciclesonide which is inactivated by blood esterases as well.[41] However, the ICSs differ markedly in their oral bioavailability, although they all undergo rather extensive first-pass metabolism to less active substances when absorbed[41] (see Table 33–9). The ICSs produce dose-dependent systemic effects, contributed by the orally absorbed fraction and the fraction absorbed from the lung[2,41,49] (Table 33–13). Essentially all the drug that reaches the lung is absorbed systemically; thus, a slow absorption from the lung results in an apparent long elimination half-life and enhances topical selectivity by lowering the systemic concentration.[41] Ciclesonide and beclomethasone dipropionate differ from the other ICSs in that the parent compounds are prodrugs that are metabolized in the lung to the active compounds des-ciclesonide and beclomethasone monopropionate.[41] The potential advantage of the drugs with low oral bioavailability is obviated by using a spacer device with the MDI for the drugs with higher oral bioavailability because appropriate spacers reduce the oral dose by 80%.[41] The use of VHCs also can increase systemic activity by increasing lung delivery of drugs not absorbed significantly orally.[41] If this increase in lung deposition is 2-fold or less, it will increase systemic activity without producing a clinically important increase in efficacy, thus decreasing the therapeutic index.[41] Mouth rinsing and spitting will also reduce the oral availability and are particularly useful for DPI devices.[2,41] Although ciclesonide and its active metabolite have rapid systemic clearance suggesting an improved therapeutic index it has not yet been clearly established in clinical trials.[41]

TABLE 33-13 Effects of Inhaled Corticosteroids

Beneficial Effects	Potential Adverse Effects
Decrease eosinophil numbers	Growth retardation, skeletal muscle myopathy
Decrease mast cell numbers	Osteoporosis, fractures and aseptic necrosis of hip
Decrease T-lymphocyte cytokine production	Posterior subcapsular cataract formation and glaucoma
Inhibit transcription of inflammatory genes in airway epithelium	Adrenal axis suppression, immunosuppression
Reduce endothelial cell leak	Impaired wound healing, easy bruising, skin striae
Upregulate β_2-receptor production	Hyperglycemia/hypokalemia, hypertension
Reduce airway epithelial subbasement membrane thickening	Psychiatric disturbances

The response to ICSs is somewhat delayed. Most patients' symptoms will improve in the first 1 to 2 weeks of therapy and will reach maximum improvement in 4 to 8 weeks.[49] Improvement in baseline FEV_1 and PEF may require 3 to 6 weeks for maximum improvement, whereas improvement in BHR requires 2 to 3 weeks and approaches maximum in 1 to 3 months but may continue to improve over 1 year.[49] Most of the improvement in these parameters occurs at low to medium doses, and there is a large variability in response, with 10% of patients not demonstrating an improvement in either parameter.[49] Whether these nonresponders also show no improvement in rates of exacerbations is unknown. Maximum decrease in FeNO occurs within 2 to 3 weeks.[15,49] Sensitivity to exercise challenge decreases after 4 weeks of therapy.[49] Although single doses do not inhibit the immediate asthmatic response to antigen challenge, continued therapy for 1 week partially suppresses the response. These two latter effects are likely due to a reduction in mucosal mast cells.[49]

Local adverse effects from ICSs include oropharyngeal candidiasis and dysphonia that are dose-dependent. The dysphonia (reported in 5%–20% of patients) appears to be due to a local corticosteroid-induced myopathy of the vocal cords.[2] The use of a spacer device with MDIs can decrease oropharyngeal deposition and thus decrease the incidence and severity of local side effects.[2,49] In infants who require ICS delivery through a facemask, the parent should clean the nasal-perioral area with a damp cloth following each treatment to prevent topical candidal infections.

Systemic adverse effects can occur with any of the ICSs given in a sufficiently high dose.[49] Long-term adverse effects of greatest concern include growth suppression in children, osteoporosis, cataracts, dermal thinning, and adrenal insufficiency and crisis.[49] Of these, only growth retardation occurs in low to medium doses. However, the growth reduction appears to be transient in that growth velocity is reduced in the first 6 months to 1 year of therapy and then returns to normal.[2,49] The effect is small (1–2 cm total) and not cumulative, and current studies suggest that attainment of predicted adult height is not affected.[2,49] The suppression of the hypothalamic-pituitary-adrenal axis and decreased bone mineralization are dose dependent and do not appear to be significant clinically except at high doses.[49] The risks therefore depend on the therapeutic index of each ICS and its delivery device. The effect of delivery device is illustrated by fluticasone propionate, which has both the greatest therapeutic index when administered by DPI and the lowest therapeutic index when administered by MDI plus VHC.[41] Many of the ICSs, including fluticasone propionate, budesonide, ciclesonide, and mometasone furoate, are metabolized in the gastrointestinal tract and liver by CYP3A4 isoenzymes. Potent inhibitors of CYP3A4 such as ritonavir and ketoconazole have the potential for increasing systemic concentrations of these ICSs by increasing oral availability and decreasing systemic clearance.[41] Some cases of clinically significant Cushing syndrome and secondary adrenal insufficiency have been reported.[41]

Most patients with moderate disease can be controlled with twice-daily dosing of most ICSs.[2,41] Twice-daily dosing produces less

thrush than 3- to 4-times-daily dosing regimens. In milder asthma, once-daily dosing is often sufficient to maintain control.[41] Some of the newer products have gained once-daily dosing indications, particularly in mild asthma once initial control is established.[41] There does not appear to be any specific pharmacologic or pharmacokinetic aspect of the ICSs that allows for once-daily dosing because all the agents studied (both the older low-potency and newer high-potency ICSs) have been effective, provided that patients had relatively mild to moderate asthma.[41] More severe patients require multiple daily dosing. The inflammatory response of asthma has been shown to inhibit corticosteroid-receptor binding.[41] This provides strong theoretical evidence for initially beginning patients on higher and more frequent doses and then tapering down once control has been achieved. Once asthma is controlled many patients are able to reduce the ICS dose and maintain control.[49]

Long-Acting Inhaled β_2-Agonists

The two LABAs, formoterol and salmeterol, provide long-lasting bronchodilation (≥12 hours) when administered as aerosols[38] (see Table 33–8). Unlike the more water-soluble short-acting β_2-agonists, the long-acting agents are lipid soluble, readily partitioning into the outer phospholipid layer of the cell membrane.[38] The LABA, are more β_2-selective than albuterol and more bronchoselective by virtue of its property of remaining in the lung tissue cell membrane, which produces its longer duration.[31] However, both formoterol and salmeterol will produce dose-dependent systemic β_2-agonist effects.[31]

The principal differences between formoterol and salmeterol are that formoterol has a more rapid onset of action and formoterol has greater agonist activty. These differences are unlikely to produce clinically significant differences because both are recommended for chronic therapy only in combination with ICSs.[6] LABAs are available singly and as fixed-dose combinations with ICSs (see below). Neither has approved FDA labeling for acute relief of asthma, although formoterol has an onset of activity similar to albuterol. Patients need to be counseled to continue to use their short-acting inhaled β_2-agonists for acute exacerbations while receiving the LABAs.

The LABAs are preferred adjunctive therapy to ICSs in children 12 years and older and adults for step 3 and children 5 to 11 years of age for steps 4 and 5.[2] Combination treatment with ICS/LABA provides greater asthma control than increasing the dose of ICS alone, while at the same time reducing the frequency of mild and severe exacerbations.[51,52] Since they are devoid of antiinflammatory activity, LABAs should not be used as monotherapy for asthma. Patients treated with LABA monotherapy added to usual therapy are at an increased risk for severe, life-threatening exacerbations and asthma-related death.[55,56] This risk may be greater in African American patients. Whether this risk is obviated by concomitant ICS use is unknown at this time but current evidence does not support an increased risk of severe, life-threatening exacerbations in patients receiving LABAs in combination with ICSs.[55–57] A recent controlled study failed to detect lung function deterioration or increased exacebations in Arg-16 homozygotes receiving a LABA plus ICS.[58]

As with short-acting β_2-agonists, tolerance is produced with chronic administration of LABAs. Long-term trials have shown no diminution in bronchodilator response but a partial loss of the bronchoprotective effect against methacholine, histamine, and exercise challenge.[31] In particular, the duration of protection against EIB following a single dose of salmeterol is up to 9 hours but is reduced to less than 4 hours following regular treatment.[31] Following regular treatment with LABAs, decreased protection against nonspecific bronchoprovocation with methacholine also occurs, although they continue to provide greater protection than placebo.[31] Responsiveness to short-acting β_2-agonists has been reported to be slightly decreased but easily overcome by increasing the dose (by approximately one puff) following chronic therapy with LABAs.[31]

There is ample evidence that the use of a LABA in combination with ICS therapy does not mask inflammation.[31] In children 4 to 11 years of age, LABAs added to ICS reduce impairment but have yet to be adequately studied for reducing the risk domain of exacerbations over ICS alone.[31,56] In children 0 to 4 years, the LABA/ICS combination has not been studied.[2]

Methylxanthines

Methylxanthines have been used for asthma therapy for more than 50 years, but their use in recent years has declined markedly owing to the high risk of severe life-threatening toxicity and numerous drug interactions, as well as decreased efficacy compared with ICSs and LABAs. Theophylline, the primary methylxanthine of interest, is a moderately potent bronchodilator with mild antiinflammatory properties.[2] Like the β_2-agonists, the methylxanthines are functional antagonists of bronchospasm; however, their clinical utility is limited by their low therapeutic index.[2] Theophylline as a sustained-release product is the preferred oral preparation, whereas its complex with ethylenediamine (aminophylline) is the preferred injectable product owing to increased solubility.[2]

The mechanism by which theophylline produces bronchodilation appears to be through nonselective phosphodiesterase inhibition–producing increased cAMP and cyclic guanosine monophosphate (cGMP) concentrations.[2] The phosphodiesterase (PDE) isoenzymes currently thought to be important for theophylline's clinical effects are isoenzymes III, predominant in airway smooth muscle, and IV, important in inflammatory cell regulation such as mast cells, neutrophils, eosinophils, and T-lymphocytes.[2] Selective PDE isoenzyme IV inhibitors, however, have no significant effects in clinical asthma. Theophylline also activates histone deacetylase that is involved in the corticosteroid-induced decrease in proinflammatory gene expression.[59] Theophylline is a competitive antagonist of adenosine and stimulates endogenous catecholamine release which are important determinants of toxic symptoms of excess theophylline.[2]

Theophylline has a log-linear dose-response curve.[60] Most chronic stable patients with asthma will obtain significant bronchodilation when the serum theophylline concentration reaches 5 mcg/mL, and most patients will have no toxic symptoms with serum concentrations of less than 15 mcg/mL.[2,60] The percentage of patients experiencing adverse effects increases sharply as concentrations exceed 15 mcg/mL. As with the β_2-agonists, the dose-response curves for smooth muscle relaxation by theophylline are dynamic and shifted to the right in the face of increasing contractile stimuli.[60] This property probably explains theophylline's relative lack of bronchodilatory effect in acute severe asthma.[2,60] The severity of theophylline's toxicity precludes even doubling the usual dosage. Toxicities include caffeine-like effects of nausea, vomiting, tachycardia, jitteriness, and difficulty sleeping to more severe toxicities such as cardiac tachyarrythmias and seizures. Death has occurred in children receiving their usual doses of theophylline during acute systemic viral illnesses.[60]

Routine monitoring of serum concentrations is essential for the safe and effective use of theophylline.[2] Theophylline is eliminated primarily by metabolism via the hepatic cytochrome P450 mixed-function oxidase microsomal enzymes (primarily the CYP1A2 and CYP3A3 isozymes), with 10% or less excreted unchanged in the kidney.[2] Theophylline clearance is age-dependent, with 1- to 9-year-olds having the highest systemic clearances and therefore

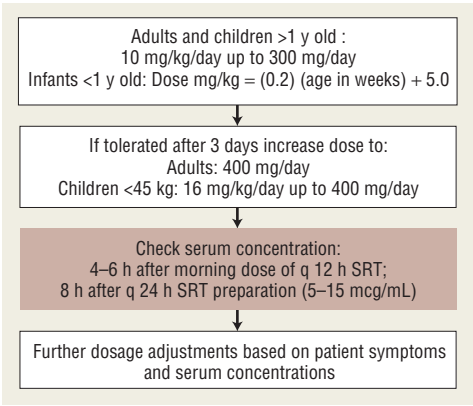

FIGURE 33-9. Algorithm for slow titration of theophylline dosage and guide for final dosage adjusment based on serum theophylline concentration measurement. For infants younger than 1 year of age, the initial daily dosage can be calculated by the following regression equation: Dose (mg/kg) = (0.2) (age in weeks) + 5.0. Whenever side effects occur, dosage should be reduced to a previously tolerated lower dose.

requiring the largest dosages (on a weight basis). However, even within the same age groups, theophylline clearance can vary 2- to 3-fold.[2] Figure 33–9 outlines a dosing and monitoring schedule for theophylline. Factors affecting theophylline's hepatic metabolism are listed in Table 33–14.[2] Only drugs or diseases that produce a ≥20% inhibition or a ≥50% induction of theophylline metabolism are likely to result in clinically significant interactions.[60]

Sustained-release theophylline is less effective than ICSs and no more effective than oral sustained-release β_2-agonists, cromolyn, or leukotriene antagonists.[2] The addition of theophylline to ICSs is similar to doubling the dose of the ICS and is overall less effective than the LABAs as adjunctive therapy.[2] The addition of theophylline to patients with poorly controlled asthma receiving ICS/LABA combination does not improve outcomes.[61]

Cromolyn Sodium

Cromolyn is classified as a mast cell stabilizer and inhibits the early and late asthmatic response to allergen challenge, as well as inhibiting exercise-induced bronchospasm.[44,62] Treatment prevents the usual rise in BHR with specific pollen seasons, but long-term treatment produces minimal to no change in baseline BHR.[2] Cromolyn inhibits neurally mediated bronchoconstriction through C-fiber sensory nerve stimulation in the airways, although it does not have a bronchodilatory effect.[62]

Cromolyn is only effective by inhalation.[62] It is not bioavailable orally, but the portion of the dose that reaches the lung is absorbed completely.[62] Absorption from the airway is significantly slower than elimination (hours vs minutes). The short duration in the lung likely limits its efficacy. Both the intensity and duration of protection against various challenges are dose dependent.[62]

Cromolyn is remarkably nontoxic. No evidence of mutagenesis or teratogenesis has been found. Cough and wheeze have been reported following inhalation.[2] Tolerance to cromolyn has not been demonstrated. It is not considered to be an ICS-sparing agent.

Cromolyn is no more or less effective than theophylline or the leukotriene antagonists for persistent asthma.[2,60] Cromolyn is not as effective as the ICSs for controlling persistent asthma.[60] Cromolyn is not as effective as the inhaled β_2-agonists for preventing EIB but can be used in conjunction for patients not responding completely to the inhaled β_2-agonists.[44]

Most patients will experience an improvement in 1 to 2 weeks, but it may take longer to achieve maximum benefit. Patients initially should receive cromolyn 4 times daily, and then only after stabilization of symptoms may the frequency be reduced to 3 times daily.

TABLE 33-14 Factors Affecting Theophylline Clearance

Decreased Clearance	% Decrease	Increased Clearance	% Increase
Cimetidine	−25 to −60	Rifampin	+53
Macrolides: erythromycin, TAO, clarithromycin	−25 to −50	Carbamazepine	+50
		Phenobarbital	+34
		Phenytoin	+70
Allopurinol	−20	Charcoal-broiled meat	+30
Propranolol	−30		
Quinolones ciprofloxacin, enoxacin, perfloxacin	−20 to −50	High-protein diet	+25
		Smoking	+40
Interferon	−50	Sulfinpyrazone	+22
Thiabendazole	−65	Moricizine	+50
Ticlopidine	−25	Aminoglutethimide	+50
Zileuton	−35		
Systemic viral illness	−10 to −50		

Leukotriene Modifiers

Two cysteinyl leukotriene receptor antagonists (zafirlukast and montelukast) and one 5-lipoxygenase inhibitor (zileuton) are available in the United States.[63] In challenge studies, they reduce allergen-, exercise-, cold-air hyperventilation-, irritant-, and aspirin-induced asthma.[63] Clinical use of zileuton is limited due to the potential for elevated liver enzymes (especially in the first 3 months of therapy), and the potential inhibition of drugs metabolized by the CYP3A4 isoenzymes.[60,63] They are not preferred alternatives in mild persistent asthma nor as alternative add-on therapy for moderate persistent asthma (Fig. 33–8).[2]

These drugs improve pulmonary function tests (FEV_1 and PEF), decrease nocturnal awakenings and β_2-agonist use, and improve asthma symptoms.[63] A major advantage is that they are effective orally, and can be administered once or twice a day.[63] However, they are less effective in asthma than low doses of ICSs.[60,63] Although montelukast is approved for EIB in adults, it is significantly less effective than short-acting inhaled β_2-agonists. In adults with severe uncontrolled asthma they do not improve outcomes.[61] They are not as effective as LABAs when added to ICSs for moderate persistent asthma.[63] It is not yet possible to predict which patients respond best to leukotriene modifiers, although there is some evidence that patients with aspirin-sensitive asthma do well, as predicted by studies showing increased cysteinyl leukotriene production in these patients.[63] It is possible that genetic polymorphisms in the 5-lipoxygenase or LTC_4 synthase pathways or in cys-LT_1 receptors might predict better responders in the future.[63] Antileukotrienes also have modest efficacy in allergic rhinitis.

In general, the LTD_4 receptor antagonists are well tolerated and do not appear to have serious class-specific effects.[2] An idiosyncratic syndrome similar to the Churg-Strauss syndrome, with marked circulating eosinophilia, heart failure, and associated eosinophilic vasculitis, has been reported in a small number of patients treated with zafirlukast and montelukast.[60] The majority of these patients had been receiving high-dose ICS or oral corticosteroids and were able to reduce the dose as a consequence of the LTD_4 receptor antagonists. It is unclear whether the increased reports are due to increased

case findings among patients with asthma prescribed a new drug or whether the syndrome is related to corticosteroid dose reduction or an idiosyncratic effect of leukotriene modifiers in general. Whatever the cause, it appears to be a rare syndrome, with an estimated incidence of fewer than 1 case per 15,000 to 20,000 patient-years of treatment.[60]

Reports of adverse neuropsychiatric events have caused the manufacturers of the leukotriene inhibitors to revise their labeling. However, evidence for causality of suicidal thoughts and suicide is lacking.[64] Reports of fatal hepatic failure associated with zafirlukast have prompted a warning for patients to be made aware of signs and symptoms of hepatic dysfunction.[2]

Zileuton can be administered twice daily as controlled release tablets.[2] Efficacy data is more limited, liver function monitoring is recommended, and drug interactions are reported with warfarin and theophylline.

Anti-IgE (Omalizumab)

Omalizumab is a recombinant anti-IgE antibody approved for the treatment of allergic asthma not well controlled on oral corticosteroids or ICSs.[65] Omalizumab is a composite of 95% human and 5% antihuman murine IgE sequences. Omalizumab binds to the Fc portion of the IgE antibody preventing the binding of IgE to its high-affinity receptor (FcεRI) on mast cells and basophils. The decreased binding of IgE on the surface of mast cells leads to a decrease in the release of mediators in response to allergen exposure. Omalizumab also decreases FcεRI expression on basophils and airway submucosal mast cells over 8 to 12 weeks.[65]

Omalizumab is administered subcutaneously and has a slow absorption rate; peak serum concentration is achieved in 3 to 14 days.[65] It is eliminated primarily through the reticuloendothelial system and has an elimination half-life of 17 to 22 days; serum free IgE levels return to baseline in about 3 weeks.[65] It should be administered under medical observation with drugs for treating anaphylaxis available.

The dosage of omalizumab is determined by the patient's baseline total serum IgE level (international units per milliliter) and body weight (kilograms).[65] Doses range from 150 to 375 mg and are given at either 2- or 4-week intervals. No further adjustments for variations in total serum IgE are required, and patients receive a consistent dose for the duration of treatment.[65] Omalizumab is approved for patients greater than 12 years with allergic asthma.[65] Clinical trials in 5- to 12-year-olds are ongoing. Due to its significant cost, it is only indicated as step 5 or 6 care for patients who have allergies and severe persistent asthma that are inadequately controlled with the combination of high dose ICS/LABA and at risk for severe exacerbations.[2,66] It is the only adjunctive therapy that has demonstrated improved outcomes in patients uncontrolled on ICS/LABA and has allowed oral corticosteroid reduction in a number of studies.[2,65] Omalizumab therapy is associated with a 0.2% rate of anaphylaxis prompting an FDA warning that patients should remain in the healthcare provider's office for a reasonable period of time past the injection as 70% of reactions occur within 2 hours. In addition, patients should be counseled on the signs and symptoms of anaphylaxis because some reactions have occurred up to 24 hours following an injection.[2,65]

MISCELLANEOUS THERAPIES (IMMUNOMODULATORS)

The following therapies have been loosely categorized by the NAEPP with omalizumab as immunomodulators because they either affect the immune system or have antiinflammatory properties. Many have been used experimentally in severe persistent uncontrolled asthma for years to try to avoid or lower oral corticosteroid dosages.

Low-dose methotrexate (15 mg/wk) used for inflammatory diseases, psoriatic and rheumatoid arthritis, and polymyositis has been used to reduce the systemic corticosteroid dose in patients with severe steroid-dependent asthma.[67] A meta-analysis of all studies determined that there was insufficient evidence to support its use, particularly in light of the risk for severe side effects.[67] Low-dose weekly methotrexate is associated with hepatotoxicity and pulmonary fibrosis.[67] The NAEPP has concluded that it should not be used in persistent asthma.[2]

A number of the drugs with antiinflammatory or immunomodulatory activity such as hydroxychloroquine, dapsone, gold, intravenous gamma-globulin, cyclosporine, and colchicine have been studied in severe corticosteroid-dependent asthma with mixed and limited results.[2,68] Routine use is not recommended.[2]

FUTURE THERAPIES

Agents that are now in development for asthma focus on the treatment of allergic inflammation.[69] Examples include inhibitors of eosinophilic inflammation, drugs that may inhibit allergen presentation, and inhibitors of Th_2 cells. Multiple cytokines have been implicated in allergic inflammation, and several possible inhibiting approaches are being explored. These range from drugs that inhibit cytokine synthesis (cyclosporin A and tacrolimus), humanized blocking antibodies to cytokines or their receptors, soluble receptors to mop up secreted cytokines, receptor antagonists, and drugs that block the signal-transduction pathways activated by cytokines.[69] Unfortunately specific anticytokine therapy against IL-5 and IL-4 have been disappointing to date.[69]

A FDA has approved Asthmatx Inc.'s Alair Bronchial Thermoplasty System to treat severe asthma in adult patients. This is the first nondrug treatment for asthma. The Alair treatment (3 sessions of 30 minutes each) is performed via a bronchoscope that is inserted into the lungs. A tip of a small catheter then expands to deliver thermal energy to reduce the presence of airway smooth muscle that narrows the airways.[70]

PHARMACOECONOMIC CONSIDERATIONS

Of the estimated $19.7 billion cost of asthma in the United States in 2004, direct medical expenditure accounted for $14.7 billion of the total, with emergency care (ED and in-patient hospital care) reaching $4.7 billion.[3] A cost-of-illness approach takes in all measurable costs; both indirect costs or costs to society and direct medical costs are considered.[71,72] Using this approach, indirect costs such as lost work and death accounted for 25% of total expenditures per patient. Although prescription drugs were the largest single direct medical expenditure at $6.7 billion,[3] an increase in these costs secondary to improved patient adherence could significantly reduce other costs due to missed school days and lost productivity secondary to asthma morbidity and mortality.

The medication cost increase over the past years resulted from an increase in prescribed medications, as well as an increase in unit cost per medication. Asthma severity affects cost of care as studies from health-maintenance organizations suggest that up to 45% of the cost of asthma is accrued by 10% of the patients, primarily as a result of emergency care.[72]

Numerous studies have demonstrated the cost-effectiveness of patient education programs for asthma, particularly those providing guided self-management.[2] Several studies have reported positive results from pharmacist interventions reducing overall cost of care.[2] Similar studies have demonstrated the cost-effectiveness of specialist care compared with generalist care. However, the results of these trials may be confounded by changes in prescribing as part of the

overall program.[71] Indeed, use of ICSs reduces both morbidity, particularly hospitalizations, and mortality in asthma patients.[2,71]

The NAEPP recommendations provide numerous alternatives for long-term controllers in mild to moderate persistent asthma, and few studies have compared their relative cost-effectiveness. This comparison is important because outside the realm of randomized clinical trials that evaluate efficacy, other factors such as concern about adverse effects and adherence to therapy may alter the overall clinical effectiveness. Use of ICSs in children has produced a cost of $9.45 per symptom-free day gained and in adults $5.00 per symptom-free day.[2] Retrospective analyses of large managed-care-linked pharmacy claims and healthcare utilization databases has allowed direct comparisons of the various long-term controllers in a general population to assess clinical effectiveness and cost-effectiveness. While these studies have confirmed comparative randomized clinical trials showing ICSs to be significantly more cost-effective than leukotriene antagonists, many have flaws, including the short duration of followup for a chronic illness such as asthma.[71]

CLINICAL CONTROVERSY

The potential for chronic use of inhaled β_2-agonists to worsen asthma has been a concern for more than 30 years. Large multicenter, double-blind, placebo-controlled trials with both mild and moderate persistent asthma have not shown that regular administration with short-acting inhaled β_2-agonists worsened asthma. However, studies that have genotyped patients at the β-receptor suggest that homozygous Arg-16 patients (who make up about 16% of the population) are predisposed to worsening asthma with regular administration as measured by lower morning PEFs.[31,39] This phenomenon does not appear to occur with as-needed therapy with short-acting β_2-agonists. Regular treatment with LABAs does not produce similar effects.[58] The Arg-16 patients still respond acutely to the β_2-agonists without diminished response. Since the regular use of short-acting inhaled β_2-agonists does not improve control of symptoms, they should be used only for relief of symptoms.[2] The LABAs should be used only in combination with ICSs where the risk of severe life-threatening exacerbations has not been demonstrated.[56,57]

EVALUATION OF ASTHMA CONTROL

Control of asthma is defined as reducing both impairment and risk domains.[71] The stepwise approach to therapy should be used to achieve and maintain this control. The steps of care appropriate to the three age ranges of asthma have been outlined in Figure 33–8.[2] Depending on the severity of the patient's asthma, compromises from the ideal control are made, and the best possible outcome balancing disease control and possible adverse effects from the drugs is attempted. Regular follow-up contact is essential (at 1–6 month intervals, depending on control). A step-down in therapy can be considered, if well-controlled status has been achieved for at least 3 months.[2]

Components of control classification include symptoms, nighttime awakenings, interference with normal activities, pulmonary function, quality of life, exacerbations, medication adherence, treatment-related adverse effects, and satisfaction with care.[71] The categories of well controlled, not well controlled, and very poorly controlled are recommended.[6] Validated questionnaires such as the Asthma Therapy Assessment Questionnaire (ATAQ), the Asthma Control Questionnaire (ACQ), and the Asthma Control Test (ACT) can be regularly administered.[71] The NAEPP minimally recommends spirometric tests at initial assessment, after treatment is initiated, and then every 1 to 2 years.[2] In moderate to severe persistent asthma, PEF monitoring is recommended. PEF monitoring should also be considered in patients who are poor symptom perceivers or those with a history of severe exacerbations.[2] Patients should also be asked about exercise tolerance. All patients on inhaled drugs should have their inhalation delivery technique evaluated periodically—monthly initially and then every 3 to 6 months, before step-up in therapy, adherence, environmental control, and comorbid conditions should be reviewed.[2]

Following initiation of antiinflammatory therapy or an increase in dosage, most patients should begin experiencing a decrease in symptoms in 1 to 2 weeks and achieve maximum symptomatic improvement within 4 to 8 weeks. The use of higher ICS doses or more potent agents may accelerate the process. Improvement in FEV_1 and PEF should follow a similar time frame; however, a decrease in BHR, as measured by morning PEF, PEF variability, and exercise tolerance, may take longer and improve over 1 to 3 months.[2] Patients should be informed that following a viral respiratory infection, they may experience decreased exercise tolerance for up to 4 weeks.

Initial visits with the patient should focus on the patient's concerns, expectations, and goals of treatment. Basic education should focus on asthma as a chronic lung disease, the types of medications, and how they are to be used. Inhaler technique is taught, as is when to seek medical advice. Written action plans should be provided. Either peak flow-based or symptom-based self-monitoring can be effective, if taught and followed correctly.[2] The first follow-up visit should be in 2 to 6 weeks, to evaluate control. At that time, the educational messages of the first visit should be repeated, as well as review of the patient's current medications, adherence, and any difficulties related to the therapy.

CONCLUSION

Asthma is a complicated disease with a multitude of clinical presentations. The exact defect in asthma has not been defined, and it may be that asthma is a common presentation of a heterogeneous group of diseases. Asthma is defined and characterized by excessive reactivity of the bronchial tree to a wide variety of noxious stimuli. The reaction is characterized by bronchospasm, excessive mucus production, and inflammation. The central role of inflammation in inducing and maintaining BHR is now becoming widely appreciated. The goal of asthma therapy is to normalize, as much as possible, the patient's life and prevent chronic irreversible lung changes. Drugs are the mainstay of asthma management. The goal of drug therapy is to use the minimum amount of medications possible to completely control the disease. In persistent asthma, therapy should be aimed at both bronchospasm and inflammation in order to produce the best results. Patients should be followed and monitored diligently for toxicities. Although death from asthma is an uncommon event, the most common cause of death is under assessment of the severity of obstruction either by the patient or by the clinician; the next common cause is undertreatment. A cornerstone of any therapy is education and the realization that most asthma deaths are avoidable.

ABBREVIATIONS

ACTH: adrenocorticotropic hormone

Arg: arginine

BAL: bronchoalveolar lavage

BHR: bronchial hyperresponsiveness
CFC: chlorofluorocarbon
cAMP: cyclic adenosine monophosphate
CYP: cytochrome P450
DPI: dry powder inhaler
ED: emergency department
EIB: exercise-induced bronchospasm
FDA: Food and Drug Administration
FeNO: fraction of exhaled nitric oxide
FEV_1: forced expiratory volume in 1 second
FVC: forced vital capacity
GINA: Global Initiative for Asthma
Gln: glutamine
Glu: glutamic acid
Gly: glycine
GM-CSF: granulocyte-macrophage colony-stimulating factor
HFA: hydrofluoroalkane
ICAM-1: intercellular adhesion molecule 1
ICS: inhaled corticosteroids
IgE: immunoglobulin E
IL: interleukin
iNOS: inducible nitric oxide synthase
LABA: long-acting β-agonists
LT: leukotriene
MDI: metered-dose inhaler
MMAD: mass median aerodynamic diameter
NAEPP: National Asthma Education and Prevention Program
NANC: nonadrenergic, noncholinergic
NO: nitric oxide
PAF: platelet-activating factor
PEF: peak expiratory flow
PKA: protein kinase
RSV: respiratory syncytial virus
SABA: short-acting β-agonists
T-cells: thymically derived lymphocytes
VCAM-1: vascular cell adhesion molecule 1
VHC: valved holding chamber
VIP: vasoactive intestinal peptide

CHAPTER 34

Chronic Obstructive Pulmonary Disease

DENNIS M. WILLIAMS AND SHARYA V. BOURDET

KEY CONCEPTS

1. Chronic obstructive pulmonary disease (COPD) is a treatable and preventable disease characterized by progressive airflow limitation that is not fully reversible and is associated with an abnormal inflammatory response of the lungs to noxious particles or gases.
2. COPD is historically described as either *chronic bronchitis* or *emphysema*. Chronic bronchitis is defined in clinical terms, whereas emphysema is defined in terms of anatomic pathology. Because most patients exhibit some features of each disease, the appropriate emphasis of COPD pathophysiology is on small airway disease and parenchymal damage that contributes to chronic airflow limitation.
3. Mortality from COPD has increased steadily over the past three decades; it currently is the fourth leading cause of death in the United States.
4. The primary cause of COPD is cigarette smoking, implicated in 85% of diagnosed cases. Other risks include a genetic predisposition, environmental exposures (including occupational dusts and chemicals), and air pollution.
5. Smoking cessation is the only management strategy proven to slow progression of COPD.
6. Oxygen therapy has been shown to reduce mortality in selected patients with COPD. Oxygen therapy is indicated for patients with a resting Pa_{O_2} of less than 55 mm Hg or a Pa_{O_2} of less than 60 mm Hg and evidence of right-sided heart failure, polycythemia, or impaired neurologic function.
7. Bronchodilators represent the mainstay of drug therapy for COPD. Pharmacotherapy is used to relieve patient symptoms and improve quality of life. Guidelines recommend short-acting bronchodilators as initial therapy for patients with mild or intermittent symptoms.
8. For the patient who experiences chronic symptoms, long-acting bronchodilators are appropriate. Either a β_2-agonist or an anticholinergic offers significant benefits. Combining long-acting bronchodilators is recommended if necessary, despite limited data.
9. The role of inhaled corticosteroid therapy in COPD is controversial. International guidelines suggest that patients with severe COPD and frequent exacerbations may benefit from inhaled corticosteroids.
10. Acute exacerbations of COPD have a significant impact on disease progression and mortality. Treatment of acute exacerbations includes intensification of bronchodilator therapy and a short course of systemic corticosteroids.
11. Antimicrobial therapy should be used during acute exacerbations of COPD if the patient exhibits at least two of the following: increased dyspnea, increased sputum volume, and increased sputum purulence.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

1 Chronic obstructive pulmonary disease (COPD) is a common lung disease characterized by airflow limitation that is not fully reversible and is both chronic and progressive. COPD is preventable and treatable and causes significant extrapulmonary effects that contribute to disease severity in a subset of patients. The prevalence and mortality of COPD have increased substantially over the past two decades. Currently, COPD is the fourth leading cause of death in the United States. By 2020, it is estimated that COPD will rank fifth in burden of disease and third as a cause of death throughout the world.

There has been a renewed interest in research and in improving clinical management recommendations for patients with COPD in recent years. Although national guidelines for management have been available for over two decades, questions were raised concerning their quality and supporting evidence. In order to standardize the care of patients with COPD and present evidence-based recommendations, the National Heart, Lung, and Blood Institute (NHLBI) and the World Health Organization (WHO) launched the Global Initiative for Chronic Obstructive Lung Disease (GOLD) in 2001.[1] This report has been updated most recently in 2009, and a full revision is expected in 2011. The goals of the GOLD organization are to increase awareness of COPD and reduce morbidity and mortality associated with the disease. International guidelines have also been developed through a collaborative effort of the American Thoracic Society (ATS) and the European Respiratory Society (ERS) and are widely available.[2] These two guidelines are generally concordant in their recommendations.

COPD is differentiated from asthma in that the airflow limitation that is present is not fully reversible. In a subset of patients, it is fixed with minimal improvement in response to a bronchodilator or with optimal treatment. However, the natural course of the disease is quite variable among patients. The chronic and progressive nature of COPD is associated with an abnormal inflammatory response of the lungs to noxious particles or gases.[2] Nonetheless, COPD is preventable and treatable. In recent years, there has been an increased appreciation for the impact of the systemic

consequences of chronic inflammatory diseases, including COPD, and for the impact of comorbidities in individual patients that can complicate COPD management.

Until recently, clinicians and researchers have exhibited a nihilistic attitude toward the value of treatments for COPD. This was based on the paucity of effective therapies, the destructive nature of the condition, and the fact that the common etiology is cigarette smoking, a modifiable health risk. There is now a renewed interest in evaluating the value of treatments and prevention based on the availability of new therapeutic options for pharmacotherapy and guidelines based on evidence.[3] The international guidelines emphasize the terms *preventable* and *treatable* to support a positive approach to managing the patient with COPD. Support is also reflected in the availability of research funding to improve understanding about this disease and its management. This includes NHLBI funding of Specialized Centers of Clinically Oriented Research (SCCOR) programs in COPD that have an objective to promote multidisciplinary research on clinically relevant questions enabling basic science findings to be more rapidly applied to clinical problems.[4]

2 The term *chronic obstructive pulmonary disease* has historically been used to describe various pulmonary diseases with a fixed component of airflow limitation. The two principal conditions are chronic bronchitis and emphysema. Chronic bronchitis is associated with chronic or recurrent excessive mucus secretion into the bronchial tree with cough that is present on most days for at least 3 months of the year for at least 2 consecutive years in a patient in whom other causes of chronic cough have been excluded.[2] While chronic bronchitis is defined in clinical terms, emphysema is defined in terms of anatomic pathology. Emphysema historically was defined on histologic examination at autopsy. Because this histologic definition is of limited clinical value, emphysema also has been defined as abnormal permanent enlargement of the airspaces distal to the terminal bronchioles accompanied by destruction of their walls yet without obvious fibrosis.[2]

Differentiating COPD as either chronic bronchitis or emphysema as descriptive subsets of COPD is no longer considered relevant. This is based on the observation that the majority of COPD is caused by a common risk factor (cigarette smoking) and most patients exhibit features of both chronic bronchitis and emphysema. Currently, emphasis is placed on the pathophysiologic features of small airways disease and parenchymal destruction as contributors to chronic airflow limitation. Most patients with COPD demonstrate features of both chronic bronchitis and emphysema. Chronic inflammation affects the integrity of the airways and causes damage and destruction of the parenchymal structures. The underlying problem is persistent exposure to noxious particles or gases that sustain the inflammatory response. The airways of both the lung and the parenchyma are susceptible to inflammation, and the result is the chronic airflow limitation that characterizes COPD (see Fig. 34–1).

EPIDEMIOLOGY

The true prevalence of COPD is likely underreported in the United States. Data from the National Health Interview Survey in 2001 indicate that 12.1 million people over age 25 years have COPD.[5] Over 9 million of these individuals have chronic bronchitis; the remaining number have emphysema or a combination of both diseases. According to national surveys, the true prevalence of people with symptoms of chronic airflow obstruction may exceed 24 million.[6] The burden may be even greater because more than one-third of adults in the United States reported respiratory complaints compatible with symptomatic COPD in some surveys.[7]

3 COPD is the fourth leading cause of death in the United States, exceeded only by cancer, heart disease, and cerebrovascular accidents. In 2005, COPD accounted for 126,005 deaths in the United States, representing one in every 20 deaths. Deaths attributed to COPD increased 8% from 2000 to 2005.[8] It is the only leading cause of death to increase over the last 30 years and is projected to be the third leading cause by 2020.[9] Overall, the mortality rate is higher in males; however, the female death rate has doubled over the last 25 years, and the number of female deaths exceeded male deaths in each year since 2000. The mortality rate is higher in whites compared with blacks.[9]

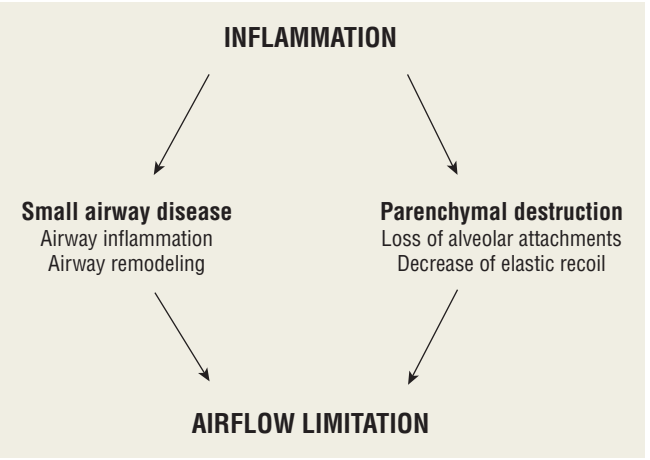

FIGURE 34-1. Mechanisms for developing chronic airflow limitation in COPD. *(From reference 1.)*

Cigarette smoking is the primary cause of COPD and, although the prevalence of cigarette smoking has declined compared with 1965, approximately 25% of individuals in the United States currently smoke. The trend of increasing COPD mortality likely reflects the long latency period between smoking exposure and complications associated with COPD.

The mortality of COPD is significant; however, morbidity associated with the disease also has a significant impact on patients, their families, and the healthcare system. COPD represents the second leading cause of disability in the United States. In the last 20 years, COPD has been responsible for nearly 50 million hospital visits nationwide.[10] In recent years, a diagnosis of COPD accounts for over 15 million physician office visits, 1.5 million emergency room visits, and 700,000 hospitalizations annually. A survey by the American Lung Association revealed that among COPD patients, 51% reported that their condition limits their ability to work, 70% were limited in normal physical activity, 56% were limited in performing household chores, and 50% reported that sleep was affected adversely.[11]

The economic impact of COPD continues to increase as well. It was estimated at $23 billion in 2000 and rose to $37.2 billion in 2004, including $20.9 billion in direct costs and $16.3 billion in indirect morbidity and mortality costs.[9,12] By 2020, COPD will be the fifth most burdensome disease, as measured by disability-adjusted life years lost due to illness. The cost of care for COPD patients is high compared with patients without the disease. There is a relationship among the severity of COPD, resources consumed, and the costs of care.[13]

ETIOLOGY

4 Cigarette smoking is the most common risk factor and accounts for 85% to 90% of cases of COPD.[1] Components of tobacco smoke activate inflammatory cells, which produce and release the inflammatory mediators characteristic of COPD. Smokers are

TABLE 34-1 Risk Factors for Development of Chronic Obstructive Pulmonary Disease (COPD)

Exposures	Host Factors
Environmental tobacco smoke	Genetic predisposition (AAT deficiency)
Occupational dusts and chemicals	Airway hyperresponsiveness
Air pollution	Impaired lung growth

12 to 13 times more likely to die from COPD than nonsmokers.[14] Although the risk is lower in pipe and cigar smokers, it is still higher than in nonsmokers. Age of starting, total pack-years, and current smoking status are predictive of COPD mortality.

However, only 15% to 20% of all smokers go on to develop COPD, and not all smokers who have equivalent smoking histories develop the same degree of pulmonary impairment, suggesting that other host and environmental factors contribute to the degree of lung dysfunction. Nevertheless, the rate of loss of lung function is determined primarily by smoking status and history.[2] Children and spouses of smokers have increased risk of developing significant pulmonary dysfunction through passive smoking, also known as *environmental tobacco smoke* or *secondhand smoke.*

In addition to cigarette smoking, COPD is attributed to a combination of risk factors that results in lung injury and tissue destruction. Risk factors can be divided into host factors and environmental factors (Table 34–1), and commonly, the interaction between these risks leads to expression of the disease. Host factors, such as genetic predisposition, may not be modifiable but are important for identifying patients at high risk of developing the disease.

Environmental factors, such as tobacco smoke and occupational dust and chemicals, are modifiable factors that, if avoided, may reduce the risk of disease development. Environmental exposures associated with COPD are particles that are inhaled by the individual, which result in inflammation and cell injury. Exposure to multiple environmental toxins increases the risk of COPD. Thus, the total burden of inhaled particles (e.g., cigarette smoke as well as occupational and environmental particles and pollutants) can play a significant role in the development of COPD. In such cases, it is helpful to assess an individual's total burden of inhaled particles. For example, an individual who smokes and works in a textile factory has a higher total burden of inhaled particles than an individual who smokes and has no occupational exposure.

In nonindustrialized countries, occupational exposures may be a more common risk than cigarette smoking. These exposures include dust and chemicals such as vapors, irritants, and fumes. Reduced lung function and deaths from COPD are higher for individuals who work in gold and coal mining, in the glass or ceramic industries with exposure to silica dust, and in jobs that expose them to cotton dust or grain dust, toluene diisocyanate, or asbestos. Other occupational risk factors include chronic exposure to open cooking or heating fires.

It is unclear whether air pollution alone is a significant risk factor for the development of COPD in smokers and nonsmokers with normal lung function. However, in individuals with existing pulmonary dysfunction, significant air pollution worsens symptoms. As evidence for this, emergency department visits are increased during higher-intensity periods of air pollution.

Individuals exposed to the same environmental risk factors do not have the same chance of developing COPD, suggesting that host factors play an important role in pathogenesis.[1,2] While many not-yet-identified genes may influence the risk of developing COPD, the best documented genetic factor is a hereditary deficiency of α_1-antitrypsin (AAT). AAT-associated emphysema is an example of a pure genetic disorder inherited in an autosomal recessive pattern. Inheritance is sometimes described as autosomal codominant by some researchers, because heterozygotes can also have decreased concentrations of AAT enzyme as well.[15] The consequences of AAT deficiency are discussed in the following section as protease-antiprotease imbalance. True AAT deficiency accounts for less than 1% of COPD cases.[2]

AAT is a 42 kDa plasma protein that is synthesized in hepatocytes. A primary role of AAT is to protect cells, especially those in the lung, from destruction by elastase released by neutrophils. In fact, AAT may be responsible for 90% of the inhibition of this destructive enzyme.[16] In individuals with the most common allele (M), plasma levels of AAT are approximately 20 to 50 μmol (100 to 350 mg/dL). The protective effect of AAT in the lungs is significantly diminished when plasma levels are less than 11 μmol (80 mg/dL).[16] AAT is an acute-phase reactant, and the serum concentration can be quite variable.

Several types of AAT deficiency have been identified and are due to mutations in the AAT gene. Two main gene variants, S and Z, have been identified. For patients who are homozygous with the S variant, AAT levels are at least 60% of those of normal individuals. These patients usually do not have an increased risk of COPD compared with normal individuals. Patients with homozygous Z deficiency (ZZ), represent 95% of clinical cases[15] and have AAT levels that are 10% of those of normal individuals, while patients with heterozygous Z variant (SZ) have levels closer to 40% of those of normal individuals. Homozygous Z patients have a higher risk of developing COPD compared with heterozygous Z patients. A history of cigarette smoking increases this risk. A small number of patients have a null phenotype and are at high risk for developing emphysema because they produce virtually no AAT.

Patients with AAT deficiency develop COPD at an early age (20 to 50 years) primarily owing to an accelerated decline in lung function. Compared with an average annual decline in forced expiratory volume in 1 second (FEV_1) of 25 mL/year in healthy nonsmokers, patients with homozygous Z deficiency have been reported to have declines of 54 mL/year for nonsmokers and 108 mL/year for current smokers. Effective diagnosis is dependent on clinical suspicion, diagnostic testing of serum concentrations, and genotype confirmation.[15] Patients developing COPD at an early age or those with a strong family history of COPD should be screened for AAT deficiency. If the concentration is low, genotype testing (DNA) should be performed.

Other genes have been implicated with increased risk of developing COPD, including chromosome 2q, transforming growth factor β_1, microsomal epoxide hydrolase 1, and tumor necrosis factor α. However, there are no definite conclusions about an association other than AAT. One genetic factor that may reduce the risk of developing COPD is a polymorphism in the gene encoding for matrix metalloproteinase 12 (MMP12). A cohort of smokers with the polymorphism exhibited a lower risk for developing COPD (0.63).[17]

Two additional host factors that may influence the risk of COPD include airway hyperresponsiveness and lung growth. Individuals with airway hyperresponsiveness to various inhaled particles may have an accelerated decline in lung function compared with those without airway hyperresponsiveness. Additionally, individuals who do not attain maximal lung growth owing to low birth weight, prematurity at birth, or childhood illnesses may be at risk for COPD in the future.[1]

PATHOPHYSIOLOGY

COPD is characterized by chronic inflammatory changes that lead to destructive changes and the development of chronic airflow limitation. The inflammatory process is widespread and not only

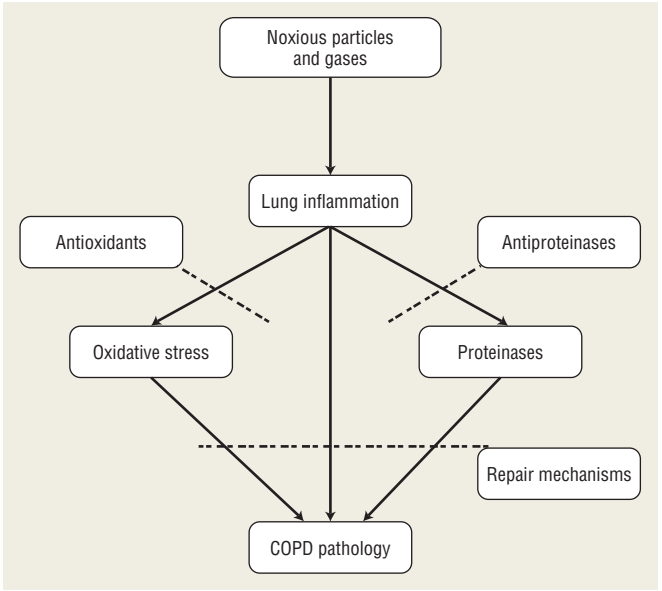

FIGURE 34-2. Pathogenesis of COPD. *(From reference 1.)*

TABLE 34-2 Features of Inflammation in COPD Compared with Asthma

	COPD	Asthma
Cells	Neutrophils Large increase in macrophages Increase in CD8+ T lymphocytes	Eosinophils Small increase in macrophages Increase in CD4+ Th2 lymphocytes Activation of mast cells
Mediators	LTB_4 IL-8 TNF-α	LTD_4 IL-4, IL-5 (Plus many others)
Consequences	Squamous metaplasia of epithelium Parenchymal destruction Mucus metaplasia Glandular enlargement	Fragile epithelium Thickening of basement membrane Mucus metaplasia Glandular enlargement
Response to treatment	Glucocorticosteroids have variable effect.	Glucocorticosteroids inhibit inflammation.

From reference 1.

involves the airways but also extends to the pulmonary vasculature and lung parenchyma. The inflammation of COPD is often referred to as *neutrophilic* in nature, but macrophages and CD8+ lymphocytes also play major roles.[18–20] The inflammatory cells release a variety of chemical mediators, of which tumor necrosis factor α (TNF-α), interleukin 8 (IL-8), and leukotriene B_4 (LTB_4) play major roles.[1,21] The actions of these cells and mediators are complementary and redundant, leading to the widespread destructive changes. The stimulus for activation of inflammatory cells and mediators is an exposure to noxious particles and gas through inhalation. The most common etiologic factor is exposure to environmental tobacco smoke, although other chronic inhalational exposures can lead to similar inflammatory changes.

Other processes that have been proposed to play a major role in the pathogenesis of COPD include oxidative stress and an imbalance between aggressive and protective defense systems in the lungs (proteases and antiproteases).[18] These processes may be the result of ongoing inflammation or occur as a result of environmental pressures and exposures (Fig. 34–2).

An altered interaction between oxidants and antioxidants present in the airways is responsible for the increased oxidative stress present in COPD. Increases in markers (e.g., hydrogen peroxide and nitric oxide) of oxidants are seen in the epithelial lining fluid.[1] The increased oxidants generated by cigarette smoke react with and damage various proteins and lipids, leading to cell and tissue damage. Oxidants also promote inflammation directly and exacerbate the protease-antiprotease imbalance by inhibiting antiprotease activity.

The consequences of an imbalance between proteases and antiproteases in the lungs were described over 40 years ago when the hereditary deficiency of the protective antiprotease AAT was discovered to result in an increased risk of developing emphysema prematurely. This enzyme (AAT) is responsible for inhibiting several protease enzymes, including neutrophil elastase. In the presence of unopposed activity, elastase attacks elastin, a major component of alveolar walls.[1]

In the inherited form of emphysema, there is an absolute deficiency of AAT. In cigarette smoking-associated emphysema, the imbalance is likely associated with increased protease activity or reduced activity of antiproteases. Activated inflammatory cells release several proteases other than AAT, including cathepsins and metalloproteinases (MMPs). In addition, oxidative stress reduces antiprotease (or protective) activity.

It is helpful to differentiate inflammation occurring in COPD from that present in asthma because the response to antiinflammatory therapy differs. The inflammatory cells that predominate differ between the two conditions, with neutrophils playing a major role in COPD and eosinophils and mast cells in asthma. Mediators of inflammation also differ with LTB_4, IL-8, and TNF-α predominating in COPD, compared with LTD_4, IL-4, and IL-5 among the numerous mediators modulating inflammation in asthma.[1] Characteristics of inflammation for the two diseases are summarized in Table 34–2.

Pathologic changes of COPD are widespread, affecting large and small airways, lung parenchyma, and the pulmonary vasculature.[1] An inflammatory exudate is often present that leads to an increase in the number and size of goblet cells and mucus glands. Mucus secretion is increased, and ciliary motility is impaired. There is also a thickening of smooth muscle and connective tissue in the airways. Inflammation is present in central and peripheral airways. The chronic inflammation results in a repeated injury and repair process that leads to scarring and fibrosis. Diffuse airway narrowing is present and is more prominent in smaller peripheral airways. The decrease in FEV_1 is attributed to the presence of inflammation in the airways, while the blood gas abnormalities result from impaired gas transfer due to parenchymal damage.

Parenchymal changes affect the gas-exchanging units of the lungs, including the alveoli and pulmonary capillaries. The distribution of destructive changes varies depending on the etiology. Most commonly, smoking-related disease results in centrilobular emphysema that primarily affects respiratory bronchioles. Panlobular emphysema is seen in AAT deficiency and extends to the alveolar ducts and sacs.

The vascular changes of COPD include a thickening of pulmonary vessels and often are present early in the disease. Increased pulmonary pressures early in the disease are due to hypoxic vasoconstriction of pulmonary arteries. If persistent, the presence of chronic inflammation may lead to endothelial dysfunction of the pulmonary arteries. Later, structural changes lead to an increase in pulmonary pressures, especially during exercise. In severe COPD, secondary pulmonary hypertension leads to the development of right-sided heart failure.

TABLE 34-3 Etiology of Airflow Limitation in COPD

Reversible
Presence of mucus and inflammatory cells and mediators in bronchial secretions
Bronchial smooth muscle contraction in peripheral and central airways
Dynamic hyperinflation during exercise
Irreversible
Fibrosis and narrowing of airways
Reduced elastic recoil with loss of alveolar surface area
Destruction of alveolar support with reduced patency of small airways

Mucus hypersecretion is present early in the course of the disease and is associated with an increased number and size of mucus-producing cells. The presence of chronic inflammation perpetuates the process, although the resulting airflow obstruction and chronic airflow limitation may be reversible or irreversible. The various causes of airflow obstruction are summarized in Table 34–3.

Recently, there has been interest in the role of thoracic overinflation as it relates to the pathophysiology of COPD. Chronic airflow obstruction leads to air trapping, which results in thoracic hyperinflation that can be detected on chest radiograph. This problem results in several dynamic changes in the chest, including flattening of diaphragmatic muscles. Under normal circumstances, the diaphragms are dome-shaped muscles tethered at the base of the lungs. When the diaphragm contracts, the muscle becomes shorter and flatter, which creates the negative inspiratory force through which air flows into the lung during inspiration. In the presence of thoracic hyperinflation, the diaphragmatic muscle is placed at a disadvantage and is a less efficient muscle of ventilation. The increased work required by diaphragmatic contractions predisposes the patient to muscle fatigue, especially during periods of exacerbations.

The other consequence of thoracic hyperinflation is a change in lung volumes. For patients with COPD who exhibit thoracic hyperinflation, there is an increase in the functional residual capacity (FRC), which is the amount of air left in the lung after exhalation at rest. Therefore, these patients are breathing at higher lung volumes, which perturbs gas exchange. In addition, the increased FRC limits the inspiratory reserve capacity, which is the amount of air that the patient can inhale to fill the lungs. The increased FRC also limits the duration of inhalation time, and this has been associated with an increase in dyspnea complaints by patients.[22] Drug therapy for COPD, especially bronchodilators, can reduce thoracic hyperinflation by reducing airflow obstruction. This may partially explain the improvement in symptoms reported by patients with COPD despite minimal improvements in lung function with drug therapy.

Airflow limitation is assessed through spirometry, which represents the "gold standard" for diagnosing and monitoring COPD. The hallmark of COPD is a reduction in the ratio of FEV_1 to forced vital capacity (FVC) to less than 70%.[1,2] The FEV_1 generally is reduced, except in very mild disease, and the rate of FEV_1 decline is greater in COPD patients compared with normal subjects.

The impact of the numerous pathologic changes in the lung perturbs the normal gas-exchange and protective functions of the lung. Ultimately, these are exhibited through the common symptoms of COPD, including dyspnea and a chronic cough productive of sputum. As the disease progresses, abnormalities in gas exchange lead to hypoxemia and/or hypercapnia, although there often is not a strong relationship between pulmonary function and arterial blood gas (ABG) results.

Significant changes in ABGs usually are not present until the FEV_1 is less than 1 L.[1] In these patients, hypoxemia and hypercapnia can become chronic problems. Initially, when hypoxemia is present, it usually is associated with exercise. However, as the disease progresses, hypoxemia at rest develops. Patients with severe COPD can have a low arterial oxygen tension (Pao_2 = 45 to 60 mm Hg) and an elevated arterial carbon dioxide tension ($Paco_2$ = 50 to 60 mm Hg). The hypoxemia is attributed to hypoventilation ($\dot{V}$) of lung tissue relative to perfusion ($\dot{Q}$) of the area. This low $\dot{V}/\dot{Q}$ ratio will progress over a period of several years, resulting in a consistent decline in the Pao_2. Some COPD patients lose the ability to increase the rate or depth of respiration in response to persistent hypoxemia. Although this is not completely understood, the decreased ventilatory drive may be due to abnormal peripheral or central respiratory receptor responses. This relative hypoventilation subsequently leads to hypercapnia. In this case, the central respiratory response to a chronically increased $Paco_2$ can be blunted. These changes in Pao_2 and $Paco_2$ are subtle and progress over a period of many years. As a result, the pH usually is nearly normal because the kidneys compensate by retaining bicarbonate. If acute respiratory distress develops, such as might be seen in pneumonia or a COPD exacerbation with impending respiratory failure, the $Paco_2$ may rise sharply, and the patient presents with an uncompensated respiratory acidosis.

The consequences of long-standing COPD and chronic hypoxemia include the development of secondary pulmonary hypertension that progresses slowly if appropriate treatment of COPD is not initiated. Pulmonary hypertension is the most common cardiovascular complication of COPD and can result in cor pulmonale, or right-sided heart failure.[23]

The elevated pulmonary artery pressures are attributed to vasoconstriction (in response to chronic hypoxemia), vascular remodeling, and loss of pulmonary capillary beds. If elevated pulmonary pressures are sustained, cor pulmonale can develop, characterized by hypertrophy of the right ventricle in response to increases in pulmonary vascular resistance.

The risks of cor pulmonale include venous stasis with the potential for thrombosis and pulmonary embolism. Another important systemic consequence of COPD is a loss of skeletal muscle mass and general decline in the overall health status.

While airway inflammation is prominent for patients with COPD, there is also evidence of systemic inflammation.[24] A consequence is widespread skeletal muscle dysfunction, especially in the leg muscles involved with ambulation.[25] The systemic manifestations can have devastating effects on overall health status and comorbidities. These include cardiovascular events associated with ischemia, cachexia, osteoporosis, anemia, and muscle wasting. There is some interest in the role of measuring C-reactive protein as a parameter to assess systemic inflammation and its impact on COPD severity; however, it is premature to recommend this strategy currently.[26]

PATHOPHYSIOLOGY OF EXACERBATION

The natural history of COPD is characterized by recurrent exacerbations associated with increased symptoms and a decline in overall health status. An exacerbation is defined as a change in the patient's baseline symptoms (dyspnea, cough, or sputum production) beyond day-to-day variability sufficient to warrant a change in management.[1,2] Exacerbations have a significant impact on the natural course of COPD and occur more frequently for patients with more severe chronic disease. Because many patients experience chronic symptoms, the diagnosis of an exacerbation is based, in part, on subjective measures and clinical judgment. Repeated exacerbations, especially those requiring hospitalization, are associated with an increased mortality risk.

There are limited data about pathology during exacerbations owing to the nature of the disease and the condition of patients. However, inflammatory mediators including neutrophils and

eosinophils are increased in the sputum. Chronic airflow limitation is a feature of COPD and may not change remarkably even during an exacerbation.[1] The lung hyperinflation present in chronic COPD is worsened during an exacerbation, which contributes to worsening dyspnea and poor gas exchange.

The primary physiologic change is often a worsening of ABG results owing to poor gas exchange and increased muscle fatigue. For a patient experiencing a severe exacerbation, profound hypoxemia and hypercapnia can be accompanied by respiratory acidosis and respiratory failure.

CLINICAL PRESENTATION

The diagnosis of COPD is made based on the patient's symptoms, including cough, sputum production, and dyspnea, and a history of exposure to risk factors such as tobacco smoke and occupational exposures. Patients may have these symptoms for several years before dyspnea develops and often will not seek medical attention until dyspnea is significant. A diagnosis of COPD should be considered for any patient, age 40 years or older, with persistent or progressive dyspnea, with chronic cough productive of sputum, and who exhibits an unusual or abnormal decline in activity, especially in the presence of positive cigarette smoke exposure. In addition, the presence of genetic factors, including AAT deficiency, and occupational exposures should be evaluated because approximately 15% of patients with COPD do not have a history of cigarette smoking.

The presence of airflow limitation should be confirmed with spirometry. Spirometry represents a comprehensive assessment of lung volumes and capacities. The hallmark of COPD is an FEV_1:FVC ratio of less than 70%, which indicates airway obstruction, and a postbronchodilator FEV_1 of less than 80% of predicted confirms the presence of airflow limitation that is not fully reversible.[1] There is an increased awareness that the use of a fixed ratio of less than 70% may be problematic because normal aging may affect this result; however, it continues to be the current standard. An improvement in FEV_1 of less than 12% following inhalation of a rapid-acting bronchodilator is considered to be evidence of irreversible airflow obstruction. Reversibility of airflow limitation is measured by a bronchodilator challenge, which is described in Table 34–4. The use of peak expiratory flow measurements is not adequate for the diagnosis of COPD owing to low specificity and the high degree of effort dependence; however, a low peak expiratory flow is consistent with COPD. A comprehensive discussion about spirometry can be found in Chapter 33.

TABLE 34-4 Procedures for Reversibility Testing

Preparation
Tests should be performed when patients are clinically stable and free from respiratory infection.
Patients should not have taken inhaled short-acting bronchodilators in the previous 6 hours, long-acting β-agonists in the previous 12 hours, or sustained-release theophylline in the previous 24 hours.
Spirometry
FEV_1 should be measured before bronchodilator is given.
Bronchodilators can be given by either metered-dose inhaler or nebulization.
Usual doses are 400 mcg of β-agonist, 80 mcg of anticholinergic, or the two combined.
FEV_1 should be measured again 30–45 minutes after bronchodilator is given.
Results
An increase in FEV_1 that is both greater than 200 mL and 12% above the prebronchodilator FEV_1 is considered significant.

From reference 1.

TABLE 34-5 Classification of COPD Severity

Stage I: mild
FEV_1/FVC <70%
$FEV_1 \geq 80\%$
With or without symptoms
Stage II: moderate
FEV_1/FVC <70%
50% <FEV_1 <80%
With or without symptoms
Stage III: severe
FEV_1/FVC <70%
30% <FEV_1 <50%
With or without symptoms
Stage IV: very severe
FEV_1/FVC <70%
FEV_1 <30% or <50% with presence of chronic respiratory failure or right-sided heart failure

From reference 1.

Spirometry combined with a physical examination improves the diagnostic accuracy of COPD.[7] Spirometry is also used to determine the severity of the disease, along with an assessment of symptoms and the presence of complications. A primary benefit of spirometry is to identify individuals who might benefit from pharmacotherapy to reduce exacerbations. Currently, the GOLD consensus guidelines suggest a 4-stage classification system (see Table 34–5).

Previously, guidelines have defined patients at risk for COPD who exhibit normal spirometry but experience chronic symptoms of cough or sputum production in the presence of risk factors. However, this category has been removed because there is not a reliable way to determine which patients might progress to COPD. This change was made because of inadequate evidence to identify patients who might progress to stage 1 disease. Patients with all levels of severity of COPD exhibit the hallmark finding of airflow obstruction, i.e., a reduction in the FEV_1:FVC ratio to less than 70%. FVC is the total amount of air exhaled after a maximal inhalation. The extent of reduction in FEV_1 further defines the patient with mild, moderate, severe, or very severe disease.[1]

Spirometry is the primary tool in classifying COPD according to severity. The severity of symptoms also impacts the patient dramatically. Often symptoms do not correlate well with the degree of airflow limitation. Two important factors that influence disease severity, survival, and health-related quality of life are body mass index (BMI) and dyspnea.[2] A low BMI is a systemic consequence of chronic COPD, and a BMI of less than 21 kg/m^2 is associated with increased mortality.[27]

Dyspnea is often the most troublesome complaint for the patient with COPD and often is the stimulus for the patient seeking medical attention. Dyspnea can impair exercise performance and functional capacity and is frequently associated with depression and anxiety. Together, these have a significant effect on health-related quality of life.[22] As a subjective symptom, dyspnea is often difficult for the clinician to assess. Various tools are available to evaluate the severity of dyspnea. A version of the Medical Research Council (MRC) scale, modified by the ATS, is commonly employed and categorizes dyspnea grades from 0 to 4 (see Table 34–6).[28]

While a physical examination is appropriate in the diagnosis and assessment of COPD, most patients who present in the milder stages of COPD will have a normal physical examination. In later stages of the disease, when airflow limitation is severe, patients may have cyanosis of mucosal membranes, development of "barrel chest" due to hyperinflation of the lungs, an increased respiratory rate and shallow breathing, and changes in breathing mechanics such as pursing of the lips to help with expiration or use of accessory respiratory muscles.

TABLE 34-6 Modified Medical Research Council (MRC) Dyspnea Scale

Grade 0	No dyspnea	Not troubled by breathlessness except with strenuous exercise
Grade 1	Slight dyspnea	Troubled by shortness of breath when hurrying on a level surface or walking up a slight hill
Grade 2	Moderate dyspnea	Walks slower than normal based on age on a level surface due to breathlessness or has to stop for breath when walking on level surface at own pace
Grade 3	Severe dyspnea	Stops for breath after walking 100 yards or after a few minutes on a level surface
Grade 4	Very severe dyspnea	Too breathless to leave the house or becomes breathless while dressing or undressing

From reference 2.

CLINICAL PRESENTATION

Symptoms

- Chronic cough
- Sputum production
- Dyspnea

Exposure to Risk Factors

- Tobacco smoke
- α_1-Antitrypsin deficiency
- Occupational hazards

Physical Examination

- Cyanosis of mucosal membranes
- Barrel chest
- Increased resting respiratory rate
- Shallow breathing
- Pursed lips during expiration
- Use of accessory respiratory muscles

Diagnostic Tests

- Spirometry with reversibility testing
- Radiograph of chest
- Arterial blood gas (not routine)

FEATURES OF COPD EXACERBATION

Symptoms

- Increased sputum volume
- Acutely worsening dyspnea
- Chest tightness
- Presence of purulent sputum
- Increased need for bronchodilators
- Malaise, fatigue
- Decreased exercise tolerance

Physical Examination

- Fever
- Wheezing, decreased breath sounds

Diagnostic Tests

- Sputum sample for Gram stain and culture
- Chest radiograph to evaluate for new infiltrates

PROGNOSIS

For the patient with COPD, the combination of impaired lung function and recurrent exacerbations promote a clinical scenario characterized by dyspnea, reduced exercise tolerance and physical activity, and deconditioning. These factors lead to disease progression, poor quality of life, possible disability, and premature mortality.[29] COPD is ultimately a fatal disease if it progresses and advanced directives and end-of-life care options are appropriate to consider. The primary causes of death of patients with COPD include respiratory failure, cardiovascular events or diseases, and lung cancer.[30]

The FEV_1 is the most important prognostic indicator for a patient with COPD. The average rate of decline of FEV_1 is the most useful objective measure to assess the course of COPD. The average rate of decline in FEV_1 for healthy, nonsmoking patients owing to age alone is 25 to 30 mL/year. The rate of decline for smokers is steeper, especially for heavy smokers compared with light smokers. The decline in pulmonary function is a steady curvilinear path. The more severely diminished the FEV_1 at diagnosis, the steeper is the rate of decline. Greater numbers of years of smoking and number of cigarettes smoked also correlate with a steeper decline in pulmonary function.[27] Conversely, the rate of decline of blood gases has not been shown to be a useful parameter to assess progression of the disease. Patients with COPD should have spirometry performed at least annually to assess disease progression.[31]

The survival rate of patients with COPD is highly correlated to the initial level of impairment in the FEV_1 and age. Other less important factors include degree of reversibility with bronchodilators, resting pulse, perceived physical disability, diffusing capacity (D_LCO), cor pulmonale, and blood gas abnormalities. A rapid decline in pulmonary function tests indicates a poor prognosis. Median survival is approximately 10 years when the FEV_1 is 1.4 L, 4 years when the FEV_1 is 1.0 L, and about 2 years when the FEV_1 is 0.5 L.

While ABG measurements are important, they do not carry the prognostic value of pulmonary function tests. Measurement of ABGs is more useful for patients with severe disease and is recommended for all patients with an FEV_1 of less than 40% of predicted or those with signs of respiratory failure or right-sided heart failure.[1]

Asthma is usually differentiated from COPD based on the patient's medical history, risk factors, and improvements on post-bronchodilator spirometry; however, in some cases, asthma patients exhibit COPD-like features and COPD patients exhibit asthma-like features. It is also possible for the two conditions to coexist.

CLINICAL PRESENTATION OF COPD EXACERBATION

Because of the subjective nature of defining an exacerbation of COPD, the criteria used among clinicians varies widely; however, most rely on a change in one or more of the following clinical findings: worsening symptoms of dyspnea, increase in sputum volume, or increase in sputum purulence. Acute exacerbations have a significant impact of the economics of treating COPD as well, estimated at 35% to 45% of the total costs of the disease in some settings.[32]

A widely accepted definition of an exacerbation is that it is an event in the natural course of COPD that is characterized by a worsening in baseline dyspnea, cough, and/or sputum that is beyond the normal day-to-day variation, is acute in onset, and may warrant a change in regular medication. With an exacerbation, patients using rapid-acting bronchodilators may report an increase in the frequency of use. Exacerbations are commonly staged as mild, moderate, or severe according to the criteria summarized in Table 34–7.[33]

TABLE 34-7 Staging Acute Exacerbations of COPD[a]

Mild (type 1)	One cardinal symptom[a] plus at least one of the following: URTI[b] within 5 days, fever without other explanation, increased wheezing, increased cough, increase in respiratory or heart rate >20% above baseline
Moderate (type 2)	Two cardinal symptoms[a]
Severe (type 3)	Three cardinal symptoms[a]

[a]Cardinal symptoms include worsening of dyspnea, increase in sputum volume, and increase in sputum purulence.
[b]URTI, upper respiratory tract infection.

TABLE 34-8 Goals of COPD Management

Prevent disease progression
Relieve symptoms
Improve exercise tolerance
Improve overall health status
Prevent and treat exacerbations
Prevent and treat complications
Reduce morbidity and mortality

An important complication of a severe exacerbation is acute respiratory failure. In the emergency department or hospital, an ABG usually is obtained to assess the severity of an exacerbation. The diagnosis of acute respiratory failure in COPD is made based on an acute change in the ABGs. Defining acute respiratory failure as a Pao_2 of less than 50 mm Hg or a $Paco_2$ of greater than 50 mm Hg often may be incorrect and inadequate because these values may not represent a significant change from a patient's baseline values. A more precise definition is an acute drop in Pao_2 of 10 to 15 mm Hg or any acute increase in $Paco_2$ that decreases the serum pH to 7.3 or less. Additional acute clinical manifestations of respiratory failure include restlessness, confusion, tachycardia, diaphoresis, cyanosis, hypotension, irregular breathing, miosis, and unconsciousness.

PROGNOSIS

COPD exacerbations are associated with significant morbidity and mortality. While mild exacerbations may be managed at home, mortality rates are higher for patients admitted to the hospital. In one study of patients hospitalized with COPD exacerbations, in-hospital mortality was 6% to 8%.[34] Many patients experiencing an exacerbation do not have a return to their baseline clinical status for several weeks, significantly affecting their quality of life. Additionally, as many as half the patients originally hospitalized for an exacerbation are readmitted within 6 months.[35]

It is now evident that acute exacerbations of COPD have a tremendous impact on disease progression and ultimate mortality. For exacerbations requiring hospitalizations, mortality rates range from 22% to 43% after 1 year, and 36% to 49% in 2 years.[34,36,37]

TREATMENT

Chronic Obstructive Pulmonary Disease

DESIRED OUTCOME

Given the nature of COPD, a major focus in healthcare should be on prevention. However, for patients with a diagnosis of COPD, the primary goal is to prevent or minimize progression. Specific goals of management are listed in Table 34–8. The primary goal of pharmacotherapy has been relief of symptoms, including dyspnea. However, more recently there has been increased interest in the value of therapeutic interventions that reduce exacerbation frequency and severity, as well as reduce mortality.

Optimally, these goals can be accomplished with minimal risks or side effects. The therapy of the patient with COPD is multifaceted and includes pharmacologic and nonpharmacologic strategies. Appropriate measures of effectiveness of the management plan include continued smoking cessation, symptom improvement, reduction in FEV_1 decline, reduction in the number of exacerbations, improvements in physical and psychological well-being, and reduction in mortality, hospitalizations, and days lost from work.

Unfortunately, most treatments for COPD have not been shown to improve survival or to slow the progressive decline in lung function. However, many therapies do improve pulmonary function and quality of life and reduce exacerbations and duration of hospitalization. Several disease-specific quality-of-life measures are available to assess the overall efficacies of therapies for COPD, including the Chronic Respiratory Questionnaire (CRQ) and the St. George's Respiratory Questionnaire (SGRQ). These questionnaires measure the impact of various therapies on such disease variables as severity of dyspnea and level of activity. They do not measure impact of therapies on survival. While early studies of COPD therapies focused primarily on improvements in pulmonary function measurements such as FEV_1, there is a trend toward greater use of these disease-specific quality-of-life measures to evaluate the benefits of therapy on larger clinical outcomes.

GENERAL APPROACH TO TREATMENT

To be effective, the clinician should address four primary components of management: Assess and monitor the condition, avoidance of or reduced exposure to risk factors, manage stable disease, and treat exacerbations. These components are addressed through a variety of nonpharmacologic and pharmacologic approaches.

NONPHARMACOLOGIC THERAPY

Patients with COPD should receive education about their disease, treatment plans, and strategies to slow progression and prevent complications.[1] Advice and counseling about smoking cessation are essential, if applicable. Because the natural course of the disease leads to respiratory failure, the clinician should address end-of-life decisions and advanced directives prospectively with the patient and family.[38]

Smoking Cessation

5 Smoking cessation represents the single most important intervention in preventing the development, as well as the progression of COPD. A primary component of COPD management is avoidance of or reduced exposure to risk factors. Exposure to environmental tobacco smoke is a major risk factor, and smoking cessation is the most effective strategy to reduce the risk of developing COPD and to slow or stop disease progression. The cost-effectiveness of smoking-cessation interventions compares favorably with interventions made for other major chronic diseases.[39] The importance of smoking cessation cannot be overemphasized. Smoking cessation leads to decreased symptomatology and slows the rate of decline of pulmonary function even after significant abnormalities in pulmonary function tests have been detected (FEV_1:FVC <60%).[31] As confirmed by the Lung Health Study, smoking cessation is the only intervention proven at this time to affect long-term decline in

FEV_1 and slow the progression of COPD.[40] In this 5-year prospective trial, smokers with early COPD were randomly assigned to one of three groups: smoking-cessation intervention plus inhaled ipratropium 3 times a day, smoking-cessation intervention alone, or no intervention. During an 11-year follow-up, the rate of decline in FEV_1 among subjects who continued to smoke was more than twice the rate in sustained quitters. Smokers who underwent smoking-cessation intervention had fewer respiratory symptoms and a smaller annual decline in FEV_1 compared with smokers who had no intervention. However, this study also demonstrated the difficulty in achieving and sustaining successful smoking cessation.

Tobacco cessation has mortality benefits beyond those related to COPD. A follow-up analysis of the Lung Health Study data conducted more than 14 years later demonstrated an 18% reduction in all-cause mortality in patients that received the intervention compared with usual care.[41] Intervention patients had lower death rates due to coronary artery disease (the leading cause of mortality), cardiovascular diseases, and lung cancer, although all categories did not reach clinical significance.

Every clinician has a responsibility to assist smokers in smoking-cessation efforts. A clinical practice guideline for treating tobacco dependence from the U.S. Public Health Service (PHS) was updated in 2008.[42] The major findings and recommendations of that report are summarized in Table 34–9. An earlier report from the Surgeon General in 2004 on the health consequences of smoking broadened the scope of the detrimental effects of cigarette smoking, indicating that "Smoking harms nearly every organ of the body, causing many diseases and reducing the health of smokers in general."[14]

TABLE 34-9 Key Guideline Recommendations Regarding Tobacco Use and Dependence[42]

Tobacco dependence is a chronic disease that often requires repeated intervention and multiple attempts to quit. Effective treatments are available that can significantly improve rates of long-term abstinence.
Clinicians and healthcare delivery systems should consistently identify and document tobacco use status and treat every tobacco user.
Tobacco-dependence treatments are effective over a broad range of populations. Clinicians should encourage every patient willing to make a quit attempt to use counseling treatments and medications recommended in the guideline.
Brief tobacco-dependence treatments are effective. Clinicians should offer every patient who uses tobacco at least these brief treatments.
Individual, group, and telephone counseling are effective, and their effectiveness increases with treatment intensity. Practical counseling (problem-solving and/or skills training) and social support are especially effective and should be employed as a part of treatment.
There are numerous effective medications for tobacco dependence, and clinicians should encourage their use by patients during a quit attempt, except when medically contraindicated or with populations in which the evidence of effectiveness is insufficient (pregnancy, smokeless tobacco users, light smokers, and adolescents). Seven first-line medications (5 nicotine and 2 non-nicotine) consistently increase long-term abstinence rates. Clinicians should also consider the use of combinations as identified in the guideline.
Counseling and medication are effective when used by themselves for treating tobacco dependence. The combination of the two is more effective than either alone. Patients should be encouraged to use both counseling and medication.
Telephone quitline counseling is effective for diverse populations and offers the advantage of broad reach. Clinicians should ensure patient access to quitlines and promote quitline use.
For a tobacco user who is currently unwilling to make a quit attempt, clinicians should use motivational treatments that have been shown to be effective in increasing future quit attempts.
Tobacco-dependence treatments are both clinically effective and highly cost-effective relative to interventions for other clinical disorders. Providing coverage for these treatments increases quit rates. Insurers and purchasers should ensure that all insurance plans include the counseling and medications identified as effective in the guideline as covered benefits.

TABLE 34-10 Five-Step Strategy for Smoking-Cessation Program (5 A's)

Ask	Use systematic approach to identify all tobacco users.
Advise	Urge all tobacco users to quit.
Assess	Determine willingness to make a cessation attempt.
Assist	Provide support for the patient to quit smoking.
Arrange	Schedule follow-up and monitor for continued abstinence.

All clinicians should take an active role in assisting patients with tobacco dependence in order to reduce the burden on the individual, his or her family, and the healthcare system. It is estimated that over 75% of smokers want to quit and that one-third have made a serious effort. Yet complete and permanent tobacco cessation is difficult.[40] Counseling that is provided by clinicians is associated with greater success rates than self-initiated efforts.[42]

The PHS guidelines recommend that clinicians take a comprehensive approach to smoking-cessation counseling. Advice should be given to smokers even if they have no symptoms of smoking-related disease or if they are receiving care for reasons unrelated to smoking. Clinicians should be persistent in their efforts because relapse is common among smokers owing to the chronic nature of dependence. Brief interventions (3 minutes) of counseling are proven effective. However, it must be recognized that the patient must be ready to stop smoking because there are several stages of decision-making. Based on this, a 5-step intervention program is proposed (Table 34–10).

There is strong evidence to support the use of pharmacotherapy to assist in smoking cessation. In fact, it should be offered to most patients as part of a cessation attempt. In general, available therapies will double the effectiveness of a cessation effort. Agents that are considered first line are listed in Table 34–11. The usual duration of therapy is 8 to 12 weeks, although some individuals may require longer courses of treatment. Precautions to consider before using bupropion include a history of seizures or an eating disorder. Nicotine-replacement therapies are contraindicated for patients with unstable coronary artery disease, active peptic ulcers, or recent myocardial infarction or stroke. Nicotine patch, bupropion, and the combination of bupropion and the nicotine patch were compared with placebo in a controlled trial.[43] The treatment groups that received bupropion had higher rates of smoking cessation than the groups that received placebo or the nicotine patch. The addition of the nicotine patch to bupropion slightly improved the smoking-cessation rate compared with bupropion monotherapy. Recently, a new agent became available to assist in tobacco cessation attempts. Varenicline is a nicotine acetylcholine receptor partial agonist that has shown benefit in tobacco cessation.[44] Varenicline relieves physical withdrawal symptoms and reduces the rewarding properties of nicotine. Nausea and headache are the most frequent complaints associated with varenicline. Currently, varenicline has not been studied in combination with other tobacco-cessation therapies. Second-line agents are less effective or associated with greater side effects; however, they may be useful in selected clinical situations. These therapies include clonidine and nortriptyline, a tricyclic antidepressant.

Behavioral modification techniques or other forms of psychotherapy also may be helpful in assisting in smoking cessation. Programs that address the many issues associated with smoking (i.e., learned behaviors, environmental influences, and chemical dependence) using a team approach are more likely to be successful. The role of alternative-medicine therapies in smoking cessation is controversial. Hypnosis may aid in improving abstinence rates when added to a smoking-cessation program but appears to give little benefit when used alone. Acupuncture has not been shown to contribute to smoking cessation and is not recommended.[2]

TABLE 34-11 First-Line Pharmacotherapies for Smoking Cessation

Agent	Usual Dose	Duration	Common Complaints
Bupropion SR	150 mg orally daily for 3 days, then twice daily	12 weeks, up to 6 months	Insomnia, dry mouth
Nicotine gum	2–4 mg gum prn, up to 24 pieces daily	12 weeks	Sore mouth, dyspepsia
Nicotine inhaler	6–16 cartridges daily	Up to 6 months	Sore mouth and throat
Nicotine nasal spray	8–40 doses daily	3–6 months	Nasal irritation
Nicotine patches	Various, 7–21 mg every 24 hours	Up to 8 weeks	Skin reaction, insomnia
Varenicline	0.5 mg daily for 3 days, then 0.5 mg twice daily for 4 days, then 1 mg twice daily	12 weeks	Nausea, sleep disturbances

Other Environmental Triggers

Although cigarette smoke represents the overwhelming majority of risk for developing COPD, exposure to other environmental toxins also confer risks. Exposures to occupational dusts and fumes have been implicated as a cause of COPD in 19% of smokers and 31% of nonsmokers with COPD in the United States. In the case of known environmental hazards, primary prevention is appropriate. Policies to limit airborne exposures in the workplace and outdoors, as well as education efforts of workers and policy makers are recommended.

Pulmonary Rehabilitation

Exercise training is beneficial in the treatment of COPD to improve exercise tolerance and to reduce symptoms of dyspnea and fatigue.[1] Pulmonary rehabilitation programs are an integral component in the management of COPD and should include exercise training along with smoking cessation, breathing exercises, optimal medical treatment, psychosocial support, and health education. Pulmonary rehabilitation has no direct effect on lung function or gas exchange. Instead, it optimizes other body systems so that the impact of poor lung function is minimized. Exercise training reduces the CNS response to dyspnea, ameliorates anxiety and depression, reduces thoracic hyperinflation, and improves skeletal muscle function.[47] High-intensity training (70% maximal workload) is possible even in advanced COPD patients, and the level of intensity improves peripheral muscle and ventilatory function. Studies have demonstrated that pulmonary rehabilitation with exercise 3 to 7 times per week can produce long-term improvement in activities of daily living, quality of life, exercise tolerance, and dyspnea for patients with moderate to severe COPD.[48] Improvements in dyspnea can be achieved without concomitant improvements in spirometry. Programs using less intensive exercise regimens (2 times per week) have not been shown to be of benefit.[49]

Immunizations

Vaccines can be considered as pharmacologic agents; however, their role is described here in reducing risk factors for COPD exacerbations. Because influenza is a common complication in COPD that can lead to exacerbations and respiratory failure, an annual vaccination with the inactivated intramuscular influenza vaccine is recommended. Immunization against influenza can reduce serious illness and death by 50% in COPD patients.[50] Influenza vaccine should be administered in the fall of each year (October and November) during regular medical visits or at vaccination clinics. There are few contraindications to influenza vaccine except for a patient with a serious allergy to eggs. An oral antiinfluenza agent (oseltamivir) can be considered for patients with COPD during an outbreak for patients who have not been immunized; however, this therapy is less effective and causes more side effects.[51]

The polyvalent pneumococcal vaccine, usually administered 1 time, is widely recommended for people from 2 to 64 years of age who have chronic lung disease and for all people older than 65 years. Thus, COPD patients at any age are candidates for vaccination. Although evidence for the benefit of the pneumococcal vaccine in COPD is not strong, the argument for continued use is that the current vaccine provides coverage for 85% of pneumococcal strains causing invasive disease and the increasing rate of resistance of pneumococcus to selected antibiotics. Currently, administering the vaccine remains the standard of practice and is recommended by the Centers for Disease Control and Prevention and the American Lung Association. Repeated vaccination with the 23-valent product is not recommended for patients aged 2 to 64 years with chronic lung disease; however, revaccination is recommended for patients over 65 years of age if the first vaccination was more than 5 years earlier and the patient was younger than age 65. The GOLD guidelines recommend pneumococcal vaccine for all COPD patients 65 years and older and for patients less than 65 years only if the FEV_1 is less than 40% predicted.[52,53] In 2009, the CDC broadened their recommendations for the pneumococcal polysaccharide vaccine to include all persons ages 18 and over who smoke based on a higher risk of pneumococcal infection in these patients.

Long-Term Oxygen Therapy

6 The use of supplemental oxygen therapy increases survival in COPD patients with chronic hypoxemia. Although long-term oxygen has been used for many years for patients with advanced COPD, it was not until 1980 that data became available documenting its benefits. At that time, the Nocturnal Oxygen Therapy Trial Group published its data comparing nocturnal oxygen therapy (NOT), 12 hours per day, with continuous oxygen therapy (COT), average of 20 hours per day.[54] Among patients who were followed for at least 12 months, the results revealed a mortality rate in the NOT group that was nearly double that of the COT group (51% vs 26%). Statistical estimates of the COT group suggest that COT may have added 3.25 years to a COPD patient's life. Additional data from the Nocturnal Oxygen Therapy Trial Group revealed that COT patients had fewer (but statistically insignificant) hospitalizations, improved quality of life and neuropsychological function, reduced hematocrit, and decreased pulmonary vascular resistance.[54]

The decline in mortality with oxygen therapy was further substantiated in 1981 in a study by the British Medical Research Council that compared 15 h/day of oxygen versus no supplemental oxygen in COPD patients.[55] Patients receiving oxygen therapy for at least part of the day had lower rates of mortality than those not receiving oxygen. Long-term oxygen therapy provides even more benefit in terms of survival after at least 5 years of use, and it improves the quality of life of these patients by increasing walking distance and neuropsychological condition and reducing time spent in the hospital.[56] Before patients are considered for long-term oxygen therapy, they should be stabilized in the outpatient setting, and pharmacotherapy should be optimized. Once this is accomplished, long-term oxygen therapy should be instituted if either of two conditions exists:

1. A resting Pao_2 of less than 55 mm Hg
2. Evidence of right-sided heart failure, polycythemia, or impaired neuropsychiatric function with a Pao_2 of less than 60 mm Hg

The most practical means of administering long-term oxygen is with the nasal cannula, at 1 to 2 L/min, which provides 24% to 28% oxygen. The goal is to raise the Pao_2 above 60 mm Hg. Patient education about flow rates and avoidance of flames (i.e., smoking) is of the utmost importance.

There are three different ways to deliver oxygen, including (1) in liquid reservoirs, (2) compressed into a cylinder, and (3) via an oxygen concentrator. Although conventional liquid oxygen and compressed oxygen are quite bulky, smaller, portable tanks are available to permit greater patient mobility. Oxygen concentrator devices separate nitrogen from room air and concentrate oxygen. These are the most convenient and the least expensive method of oxygen delivery. Oxygen-conservation devices are available that allow oxygen to flow only during inspiration, making the supply last longer. These may be particularly useful to prolong the oxygen supply for mobile patients using portable cylinders. However, the devices are bulky and subject to failure.

Adjunctive Therapies

In addition to supplemental oxygen, adjunctive therapies to consider as part of a pulmonary rehabilitation program are psychoeducational care and nutritional support. Psychoeducational care (such as relaxation) has been associated with improvement in the functioning and well-being of adults with COPD.[1,2] The role of nutritional support for patients with COPD is controversial. Several studies have shown an association among malnutrition, low BMI, and impaired pulmonary status among patients with COPD. However, a metaanalysis suggests that the effect of nutritional support on outcomes in COPD is small and not associated with improved anthropometric measures, lung function, or functional exercise capacity.[57]

PHARMACOLOGIC THERAPY

Results from numerous recent clinical trials have improved insight and understanding about the respective roles of various medications used in chronic COPD management; yet, some controversies still exist related to both effectiveness and safety. In contrast to the survival benefit conferred by supplemental oxygen therapy, there is no medication available for the treatment of COPD that has been shown to modify the progressive decline in lung function or prolong survival.[1] There is limited evidence that chronic treatment with long-acting inhaled β-agonists, inhaled corticosteroids, or the combination can reduce the rate of decline in spirometry in a subset of patients with more severe disease.[58] Currently, the primary goal of pharmacotherapy is to control patient symptoms and reduce complications, including the frequency and severity of exacerbations and improving the overall health status and exercise tolerance of the patient.

International guidelines recommend a stepwise approach to the use of pharmacotherapy based on disease severity[1,2], which is determined by the extent of airflow limitation and degree of symptoms. The impact of recurrent exacerbations on accelerating disease progression is increasingly recognized as an important factor to be considered. The primary goals of pharmacotherapy are to control symptoms (including dyspnea), reduce exacerbations, and improve exercise tolerance and health status. Currently, there is inadequate evidence to support the use of more aggressive pharmacotherapy early in the course of disease because of the lack of a disease modifying benefit. Because of the progressive nature of COPD, pharmacotherapy tends to be chronic and cumulative and step down approaches in stable patients are not successful. Patients exhibit variable responses to available therapies and the treatment approach should be individualized.

Pharmacotherapy of COPD typically involves the use of inhaled medications, requiring patient knowledge, understanding, and skills using the various inhalation devices. Several delivery devices are available (e.g., metered-dose inhalers, dry powder inhalers, nebulizers, and ancillary devices such as holding chambers), and the instructions about proper use vary. Comorbidities that are common for patients with COPD, including physical and mental conditions, can have a significant effect on the patient's ability to use the devices. Periodic and frequent reinforcement and observation by the clinician is required for the patient's benefit.

7 Pharmacotherapy focuses on the use of bronchodilators to control symptoms. Bronchodilators relax bronchial smooth muscle, improve lung emptying, reduce thoracic hyperinflation at rest and during exercise, and improve exercise tolerance.[1] These effects can be seen in the absence of objective improvements on spirometry. There are several classes of bronchodilators to choose from, and no single class has been proven to provide superior benefit over other available agents. The initial and subsequent choice of medications should be based on the specific clinical situation and patient characteristics. Medications can be used as needed or on a scheduled basis depending on the clinical situation, and additional therapies should be added in a stepwise manner depending on the response and severity of disease. Considerations should be given to individual patient response, tolerabilility, adherence, and economic factors. A stepwise approach to the management of COPD has been proposed based on the stage of disease severity (Fig. 34–3).

According to the guidelines, patients with intermittent symptoms should be treated with short-acting bronchodilators. When symptoms become more persistent, long-acting bronchodilators should be initiated. For patients with an FEV_1 less than 50% and who experience frequent exacerbations, inhaled corticosteroids should be considered. Short-acting bronchodilators relieve symptoms and increase exercise tolerance. Long-acting bronchodilators relieve symptoms, reduce exacerbation frequency, and improve quality of life and health status. Patients have a variety of choices in using inhalational therapies, including metered dose inhalers (MDI), dry powder inhalers (DPI), or nebulizers. There is not a clear advantage of one delivery method over another, and it is recommended that patient-specific factors and preferences should be considered in selecting the device.[59]

Bronchodilators

Bronchodilator classes available for the treatment of COPD include β_2-agonists, anticholinergics, and methylxanthines. There is no clear benefit to one agent or class over others, although inhaled therapy generally is preferred. In general, it can be more difficult for patients with COPD to use inhalation devices effectively compared with other populations owing to advanced age and the presence of other comorbidities. Clinicians should advise, counsel, and observe patient technique with the devices frequently and consistently.

Bronchodilators generally work by reducing the tone of airway smooth muscle (relaxation), thus minimizing airflow limitation. For patients with COPD, the clinical benefits of bronchodilators include increased exercise capacity, decreased air trapping in the lungs, and relief of symptoms such as dyspnea. However, use of bronchodilators may not be associated with significant improvements in pulmonary function measurements such as FEV_1. In clinical studies, regular use of a long-acting inhaled bronchodilator (LABA or Anticholinergic) or ipratropium are associated with improved health status. Regular use of tiotropium also reduces exacerbation rates. In general, side effects of bronchodilator medications are related to their pharmacologic effects and are dose dependent. Because COPD patients are older and more likely to have comorbid

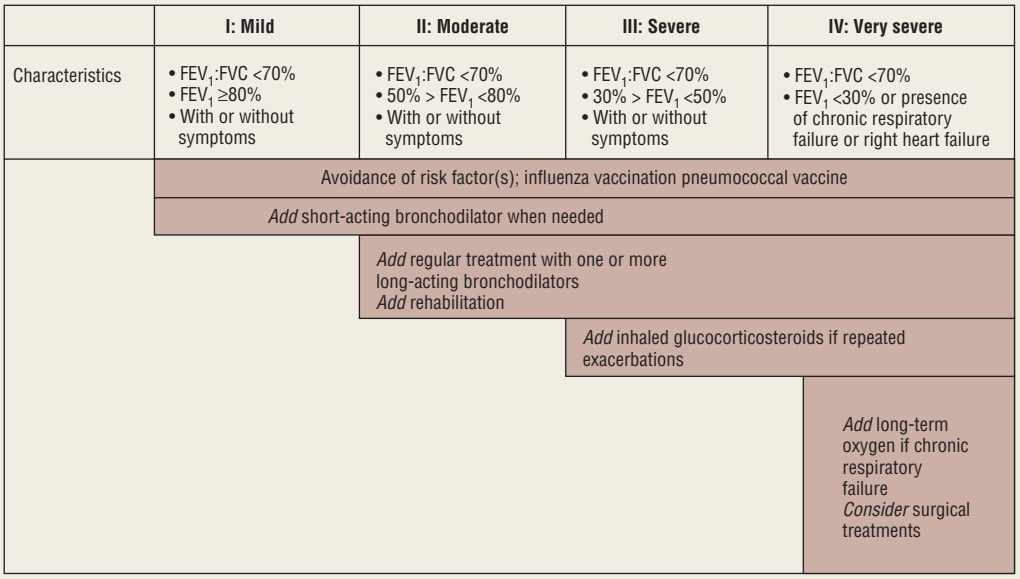

FIGURE 34-3. Recommended therapy of stable COPD. (FEV_1, forced expiratory volume in the first second of expiration; FVC, forced vital capacity.) *(From reference 1.)*

conditions, the risk for side effects and drug interactions is higher compared with patients with asthma.

Short-Acting Bronchodilators The initial therapy for COPD patients who experience symptoms intermittently are short-acting bronchodilators. Among these agents, the choices are a short-acting beta$_2$ agonist or an anticholinergic. Either class of agents has a relatively rapid onset of action, relieves symptoms, and improves exercise tolerance and lung function. In general, both classes are equally effective.

Short-Acting Sympathomimetics (β_2-Agonists) A number of sympathomimetic agents are available in the United States. They vary in selectivity, route of administration, and duration of action. In COPD management, sympathomimetic agents with β_2-selectivity, or β_2-agonists, should be used as bronchodilators. β_2-Agonists cause bronchodilation by stimulating the enzyme adenyl cyclase to increase the formation of cyclic adenosine monophosphate (cAMP). cAMP is responsible for mediating relaxation of bronchial smooth muscle, leading to bronchodilation. In addition, they may improve mucociliary clearance. Although shorter-acting and less selective β-agonists are still used widely (e.g., metaproterenol, isoetharine, isoproterenol, and epinephrine), they should not be used owing to their shorter duration of action and increased cardiostimulatory effects. Short-acting, selective β_2-agonists such as albuterol, levalbuterol, and pirbuterol are preferred for therapy.

Sympathomimetics are available in inhaled, oral, and parenteral dosage forms. The preferred route of administration is by inhalation. The use of oral and parenteral β-agonists in COPD is discouraged because they are no more effective than a properly used metered-dose inhaler (MDI) or dry-powder inhaler (DPI), and the incidence of systemic adverse effects such as tachycardia and hand tremor is greater. Administration of β_2-agonists in the outpatient and emergency room settings via inhalers (MDIs or DPIs) is at least as effective as nebulization therapy and usually favored for reasons of cost and convenience.[59] Chapter 33 includes a complete description of the devices used for delivering aerosolized medication and a comparison β_2-agonist therapies.

Albuterol is the most frequently used β_2-agonist. It is available as an oral and inhaled preparation. Albuterol is a racemic mixture of (*R*)-albuterol, which is responsible for the bronchodilator effect, and (*S*)-albuterol, which has no therapeutic effect. (*S*)-Albuterol is considered by some clinicians to be inert, whereas others believe that it may be implicated in worsening airway inflammation and antagonizing the response to (*R*)-albuterol. Levalbuterol is a single-isomer formulation of (*R*)-albuterol. A retrospective evaluation of levalbuterol versus albuterol use for patients with asthma and COPD concluded that levalbuterol offered significant advantages over albuterol for hospitalized patients.[60] Other clinicians feel that there are no significant differences between the products and that the use of levalbuterol is not justified owing to its higher acquisition cost.[61] The effects of a single dose of levalbuterol have been compared with those of albuterol and ipratropium plus albuterol for patients with COPD. No significant differences in pulmonary function improvements or adverse effects were noted.[62]

In COPD patients, β_2-agonists exert a rapid onset of effect, although the response generally is less than that seen in asthma. Short-acting inhaled β_2-agonists cause only a small improvement in FEV_1 acutely but may improve respiratory symptoms and exercise tolerance despite the small improvement in spirometric measurements.[63] Patients with COPD can use quick-onset β_2-agonists as needed for relief of symptoms or on a scheduled basis to prevent or reduce symptoms. The duration of action of short-acting β_2-agonists is 4 to 6 hours.

Inhaled β_2-agonists are generally well tolerated. They can cause sinus tachycardia and rhythm disturbances in predisposed patients, but these are rarely reported. Skeletal muscle tremors can occur initially but subside as tolerance develops.

Short-Acting Anticholinergics When given by inhalation, anticholinergics such as ipratropium or atropine produce bronchodilation by competitively inhibiting cholinergic receptors in bronchial smooth muscle. This activity blocks acetylcholine, with the net effect being a reduction in cyclic guanosine monophosphate (cGMP), which normally acts to constrict bronchial smooth muscle. Muscarinic receptors on airway smooth muscle include M_1, M_2, and

M_3 subtypes. Activation of M_1 and M_3 receptors by acetylcholine results in bronchoconstriction; however, activation of M_2 receptors inhibits further acetylcholine release.

Ipratropium is the primary short-acting anticholinergic agent used for COPD in the United States. Atropine has a tertiary structure and is absorbed readily across the oral and respiratory mucosa, whereas ipratropium has a quaternary structure that is absorbed poorly. The lack of systemic absorption of ipratropium greatly diminishes the anticholinergic side effects such as blurred vision, urinary retention, nausea, and tachycardia associated with atropine. Ipratropium bromide is available as an MDI and a solution for inhalation. The MDI was recently reformulated with an HFA propellant and delivers 17 mcg per puff. Ipratropium is also available as an MDI in combination with albuterol and as a solution for nebulization at 200 mcg/mL. It provides a peak effect in 1.5 to 2 hours and has a duration of effect of 4 to 6 hours. Ipratropium has a slower onset of action and a more prolonged bronchodilator effect compared with standard β_2-agonists. Because of the slower onset of effect (15 to 20 minutes compared with 5 minutes for albuterol), it may be less suitable for as-needed use; however, it is often prescribed in that manner. The role of inhaled anticholinergics in COPD is well established.[64–66] However, results from the Lung Health Study showed that treatment with ipratropium did not affect the progressive decline in lung function [40] Studies comparing ipratropium with inhaled β_2-agonists have generally reported similar improvements in pulmonary function. Others report a modest benefit with ipratropium, including a lower incidence of side effects such as tachycardia.[64,65]

Although the recommended dose of ipratropium is 2 puffs four times a day, there is evidence for a dose-response, so the dose can be titrated upward often to 24 puffs a day. Ipratropium has been shown to increase maximum exercise performance in stable COPD patients with doses of 8 to 12 puffs prior to exercise but not with doses of 4 puffs or less.[66,67] During sleep, ipratropium also has been shown to improve arterial oxygen saturation and sleep quality.[68] Ipratropium is well tolerated. The most frequent patient complaints are dry mouth, nausea, and an occasional metallic taste.

Clinicians differ about preference in choosing the initial short-acting bronchodilator therapy for the patient with COPD. Both a short-acting β_2-agonist and ipratropium represent reasonable choices for initial therapy.

8 Long-Acting Bronchodilators For patients with moderate to severe COPD who experience symptoms on a regular and consistent basis, or in whom short-acting therapies do not provide adequate relief, long-acting bronchodilator therapies are the recommended treatment. Long-acting inhaled bronchodilator therapy can be administered as an inhaled β_2-agonist (LABA) or an anticholinergic. Long-acting, inhaled bronchodilator therapy is more convenient and effective, compared with short-acting agents, for patients with chronic symptoms. There are superior outcomes in lung function as measured by spirometry, symptoms including dyspnea, and, importantly, reductions in exacerbation frequency and improved quality of life.

Long-Acting Inhaled β_2-Agonists (LABAs) LABAs offer the convenience and benefit of a long duration of action for patients with persistent symptoms. Each of the currently available agents, salmeterol, formoterol, and arformoterol is dosed every 12 hours and provides sustained bronchodilation. Arformoterol and formoterol has an onset of action similar to albuterol (less than 5 minutes), whereas salmeterol has a slower onset (15 to 20 minutes); however, neither agent is recommended for acute relief of symptoms. There is no dose titration for any of these agents; the starting dose is the effective and recommended dose for all patients. The clinical benefits of long-acting inhaled β_2-agonists compared with short-acting therapies include similar or superior improvements in lung function and symptoms, as well as reduced exacerbation rates in some studies.[69–71] The use of the long-acting agents should be considered for patients with frequent and persistent symptoms. When patients require short-acting β_2-agonists on a scheduled basis, LABAs are more convenient based on dosing frequency but are also more expensive. Salmeterol and formoterol are available in dry powder inhalation devices, and formoterol and arformoterol as solutions for nebulization. An ultra-long-acting agent, indacaterol, which requires once daily dosing is in phase 3 and 4 clinical trials in 2009.

LABAs are also useful to reduce nocturnal symptoms and improve quality of life. When compared with short-acting bronchodilators or theophylline, both salmeterol and formoterol improve lung function, symptoms, exacerbation frequency, and quality of life.[72] These benefits are apparent even for patients with poorly reversible lung function and are related to improvements in inspiratory capacity.[73] Both salmeterol and formoterol have been compared with ipratropium. In separate studies, each agent improved FEV_1 compared with ipratropium and, in addition, the LABA was more effective for other selected outcomes (e.g., prolonged time to exacerbation for salmeterol while formoterol reduced symptoms and rescue inhaler use).[74,75]

Long-Acting Anticholinergics Tiotropium bromide, a long-acting quaternary anticholinergic agent, has been available in the United States since 2004. This agent blocks the effects of acetylcholine by binding to muscarinic receptors in airway smooth muscle and mucus glands, blocking the cholinergic effects of bronchoconstriction and mucus secretion. Tiotropium is more selective than ipratropium at blocking important muscarinic receptors. Tiotropium dissociates slowly from M_1 and M_3 receptors, allowing prolonged bronchodilation. The dissociation from M_2 receptors is much faster, allowing inhibition of acetylcholine release. Binding studies of tiotropium in the human lung show that it is approximately 10-fold more potent than ipratropium and protects against cholinergic bronchoconstriction for greater than 24 hours.[76]

When inhaled, tiotropium is minimally absorbed into the systemic circulation and results in bronchodilation within 30 minutes, with a peak effect in 3 hours. Bronchodilation persists for at least 24 hours, allowing for a once daily dosing. There is no titration of tiotropium dose; a regimen of 18 mcg inhaled once daily is recommended for all patients. In the United States, it is delivered via the HandiHaler, a single-load, dry-powder, breath-actuated device. Because it acts locally, tiotropium is well tolerated, with the most common complaint being a dry mouth. Other anticholinergic side effects that are reported include constipation, urinary retention, tachycardia, blurred vision, and precipitation of narrow-angle glaucoma symptoms.

The benefits of tiotropium have been evaluated in numerous trials of patients with COPD. Similar to long-acting β-agonists, tiotropium improves lung function and dyspnea, exacerbation frequency, and health-related quality of life.[77] In this study, tiotropium improved FEV_1 by an average of 12% to 22% compared with placebo. The tolerance that is demonstrated with chronic use of β-agonists does not occur with tiotropium therapy, as improvements in lung function are sustained with long-term therapy.[78]

There is a large body of evidence supporting the use of tiotropium as a long acting bronchodilator for COPD patients. Benefits have been demonstrated compared with placebo[79] and to ipratropium.[80] Tiotropium therapy is associated with a decreased risk of exacerbations compared with placebo or ipratropium, and equal or superior efficacy compared with LABAs in various studies.[81]

As a long-acting bronchodilator, tiotropium is an option to consider in addition to long-acting inhaled β_2-agonists for COPD

management. Once-daily tiotropium has been compared with twice-daily salmeterol in two placebo-controlled trials of 6 months duration. Tiotropium reduced asthma exacerbations and hospital admissions and improved quality of life, whereas both active treatments improved lung function and reduced dyspnea.[79] In another 6-month randomized, controlled trial of patients with COPD, patients were randomized to receive either tiotropium once daily by DPI, salmeterol twice daily by MDI, or placebo.[82] Patients receiving tiotropium had greater improvements in trough FEV_1 and dyspnea scores than those receiving salmeterol. Patients also were more likely to have improvements in quality-of-life indicators with tiotropium than with salmeterol. However, no differences in frequency of exacerbations were noted among the three groups.

The most notable study involving the use of tiotropium in recent years for patients with COPD was the Understanding Potential Long-term Impacts on Function with Tiotropium(UPLIFT) trial.[83] This was a randomized, double-blind study of 4 years duration. A total of 5,993 subjects received either tiotropium 18 mcg daily inhaled via a HandiHaler device or a matching placebo. All other COPD therapies were allowed except for other anticholinergic therapies (e.g., ipratropium). The mean postbronchodilator FEV_1 among subjects was 1.32 L, and the primary outcome was the rate of decline in FEV_1 on spirometry. The results showed that tiotropium treatment resulted in prebronchodilator FEV_1 improvement of 87 to 103 ml, and postbronchodilator improvement of 47 to 65 mL, both of which were statistically significant. However, the rate of decline in the mean FEV_1 result was not statistically significant between the groups. Tiotropium-treated subjects benefited from treatment as reflected in improved quality-of-life scores, reduced exacerbation rates, fewer hospitalizations, and instances of respiratory failure. Tiotropium was associated with a lower overall risk of mortality, including deaths from respiratory and cardiac causes.

The safety of tiotropium documented in the UPLIFT trial is reassuring. Recently, retrospective analysis have reported an increased risk of cardiovascular events associated with ipratropium[84] and tiotropium use.[85] However, the UPLIFT study, which was a prospective trial over 4 years, did not report an increased cardiovascular risk associated with tiotropium use.[83]

Combination Anticholinergics and β-Agonists Combination regimens of bronchodilators are used often in the treatment of COPD, especially as the disease progresses and symptoms worsen over time. Combining bronchodilators with different mechanisms of action allows the lowest possible effective doses to be used and reduces potential adverse effects from individual agents.[1] Combinations of both short- and long-acting β_2-agonists with ipratropium have been shown to provide added symptomatic relief and improvements in pulmonary function.[86–88] A combination of albuterol and ipratropium (Combivent) is available as an MDI in the United States for chronic maintenance therapy of COPD. This product offers the obvious convenience of two classes of bronchodilators in a single inhaler.

Although clinical practice guidelines recommend that combinations of long-acting bronchodilators are appropriate for patients who do not receive adequate benefit from a single agent, data to support the use of these combinations have been lacking. These approaches have been the focus of more recent research. Future combination inhalation products may contain long-acting β_2-agonists with tiotropium to reduce the need for frequent dosing. In a preliminary single-dose study, the combination of tiotropium and formoterol resulted in a faster and greater improvement in FEV_1 compared with either treatment alone.[89] In another trial, 95 subjects received either tiotropium 18 mcg or tiotropium plus formoterol 12 mcg either once or twice daily. All patients received each therapy for 2 weeks each in an open label, crossover design. Both combination regimens improved lung function and reduced rescue therapy use compared with tiotropium alone.[90]

Methylxanthines Methylxanthines, including theophylline and aminophylline, have been available for the treatment of COPD for at least five decades and at one time were considered first-line therapy. However, with the availability of long-acting inhaled β_2-agonists and inhaled anticholinergics, the role of methylxanthine therapy is significantly limited. Inhaled bronchodilator therapy is preferred for COPD. Because of the risk for drug interactions and the significant intrapatient and interpatient variability in dosage requirements, theophylline therapy generally is considered for patients who are intolerant or unable to use an inhaled bronchodilator. Theophylline is still an alternative to commonly used inhaled therapies partially due to the potential for multiple mechanisms (bronchodilation and antiinflammatory) and the possible benefit that systemic administration may exert on peripheral airways.[91]

The methylxanthines may produce bronchodilation through numerous mechanisms, including (1) inhibition of phosphodiesterase, thereby increasing cAMP levels, (2) inhibition of calcium ion influx into smooth muscle, (3) prostaglandin antagonism, (4) stimulation of endogenous catecholamines, (5) adenosine receptor antagonism, and (6) inhibition of release of mediators from mast cells and leukocytes.[92]

Chronic theophylline use for patients with COPD has been shown to exert improvements in lung function, including vital capacity (VC), FEV_1, minute ventilation, and gas exchange.[91] Subjectively, theophylline has been shown to reduce dyspnea, increase exercise tolerance, and improve respiratory drive in COPD patients.[91,92] Other nonpulmonary effects of theophylline that may contribute to improved overall functional capacity for patients with COPD include improved cardiac function and decreased pulmonary artery pressure.

Although theophylline is available in a variety of oral dosage forms, sustained-release preparations are most appropriate for the long-term management of COPD. These products have the advantages of improving patient compliance and achieving more consistent serum concentrations over rapid-release theophylline and aminophylline preparations. However, caution must be used in switching from one sustained-release preparation to another because there are considerable variations in sustained-release characteristics.[92] Aside from intravenous aminophylline, there is no need to use any of the various salts forms of theophylline.

Regular use of methylxanthines has not been shown to have either a beneficial or a detrimental effect on the progression of COPD. However, methylxanthines may be added to the treatment plan of patients who have not achieved an optimal clinical response to ipratropium and an inhaled β_2-agonist. Studies suggest that adding theophylline to a combination of albuterol and ipratropium provides added benefit for stable COPD patients, supporting the hypothesis that there is a synergistic bronchodilator effect.[93–95] The efficacy of combination therapy with salmeterol and theophylline for patients with COPD was reported to improve pulmonary function and reduce dyspnea better than either treatment alone.[96] Combination treatment also was associated with a reduced number of exacerbations only when compared with the theophylline group, suggesting that the salmeterol component was responsible for this beneficial effect.

As is the case with other bronchodilator therapy, parameters other than objective measurements, such as FEV_1, should be monitored to assess efficacy of theophylline in COPD. Subjective parameters, such as perceived improvements in symptoms of dyspnea and exercise tolerance, become increasingly important in assessing the acceptability of methylxanthines for COPD patients. Although objective improvement may be minimal, patients may

experience an improvement in clinical symptoms, and thus benefit to the individual may be meaningful.

The role of theophylline in COPD is as maintenance therapy in the nonacutely ill patient. Therapy can be initiated at 200 mg twice daily and titrated upward every 3 to 5 days to the target dose. Most patients required daily doses of 400 to 900 mg. Dosage adjustments generally should be made based on serum concentration results. Traditionally, the therapeutic range of theophylline was identified as 10 to 20 mcg/mL; however, because of the frequency of dose-related side effects and the relatively minor benefit of higher concentrations, a more conservative therapeutic range of 8 to 15 mcg/mL often is targeted. This is especially preferable for the elderly. When concentrations are measured, trough measurements are most appropriate.

Once a dose is established, serum concentrations should be monitored once or twice a year unless the patient's disease worsens, medications that interfere with theophylline metabolism are added to therapy, or toxicity is suspected. The most common side effects of theophylline therapy are related to the gastrointestinal system, the cardiovascular system, and the central nervous system. Side effects are dose-related; however, there is overlap in side effects between the therapeutic and toxic ranges. Minor side effects include dyspepsia, nausea, vomiting, diarrhea, headache, dizziness, and tachycardia. More serious toxicities, especially at toxic concentrations, include arrhythmias and seizures.

Factors that decrease theophylline clearance and lead to reduced maintenance-dose requirements include advanced age, bacterial or viral pneumonia, left or right ventricular failure, liver dysfunction, hypoxemia from acute decompensation, and use of drugs such as cimetidine, macrolides, and fluoroquinolone antibiotics. Factors that may enhance theophylline clearance and result in the need for higher maintenance doses include tobacco and marijuana smoking, hyperthyroidism, and the use of such drugs as phenytoin, phenobarbital, and rifampin.

In summary, there are decades of experience with theophylline and other methylxanthine products in the management of patients with COPD. However, inhalation therapy is currently preferred based on superior efficacy and safety, as well as ease of use by the clinician. Theophylline is a challenging medication to dose, monitor, and manage due to the significant intrapatient and interpatient variability in pharmacokinetics and the potential for drug interactions and toxicities.

Corticosteroids

9 Corticosteroid therapy has been studied and debated in COPD therapy for half a century; however, owing to the poor risk-to-benefit ratio, chronic systemic corticosteroid therapy should be avoided if possible.[1] Because of the potential role of inflammation in the pathogenesis of the disease, clinicians hoped that corticosteroids would be promising agents in COPD management. However, their use continues to be debated, especially in the management of stable COPD.

The antiinflammatory mechanisms whereby corticosteroids exert their beneficial effect in COPD include (1) reduction in capillary permeability to decrease mucus, (2) inhibition of release of proteolytic enzymes from leukocytes, and (3) inhibition of prostaglandins. Unfortunately, the clinical benefits of systemic corticosteroid therapy in the chronic management of COPD are often not evident, and the risk of toxicity is extensive and far-reaching. Currently, the appropriate situations to consider corticosteroids in COPD include (1) short-term systemic use for acute exacerbations and (2) inhalation therapy for chronic stable COPD.

The role of oral steroid use in chronic stable COPD patients was evaluated in a metaanalysis over a decade ago.[97] Investigators concluded that only a small fraction (10%) of COPD patients treated with steroids showed clinically significant improvement in baseline FEV_1 (increase of 20%) compared with those treated with placebo. While a small number of COPD patients are considered responders to oral steroids, many of these patients actually may have an asthmatic, or reversible, component to their disease. The best predictors for response to oral steroids are the presence of eosinophils on sputum examination (≥3%) and a significant response to sympathomimetics on pulmonary function tests.[98] Both the presence of eosinophils in sputum and the responsiveness to sympathomimetics suggest an asthmatic component to the disease process and thus may explain the clinical benefit seen with steroids.

Long-term adverse effects associated with systemic corticosteroid therapy include osteoporosis, muscular atrophy, thinning of the skin, development of cataracts, and adrenal suppression and insufficiency. The risks associated with long-term steroid therapy are much greater than the clinical benefits. If a decision to treat with long-term systemic corticosteroids is made, the lowest possible effective dose should be given once per day in the morning to minimize the risk of adrenal suppression. If therapy with oral agents is required, an alternate-day schedule should be used.

Previously, a common clinical practice was to administer a short course (2 weeks) of oral corticosteroids as a trial to predict which patients would benefit from chronic oral or inhaled corticosteroids. There is now sufficient evidence suggesting that this practice is not effective in predicting a long-term response to inhaled corticosteroids and should not be recommended.[99]

The use of chronic inhaled corticosteroid therapy has been of interest for the past decade. Their use has been common despite the lack of firm evidence about significant clinical benefit until recently. Inhaled corticosteroids have an improved risk-to-benefit ratio compared with systemic corticosteroid therapy. Using the model for asthma, it was hoped that the inhalation of potent corticosteroid would result in high local efficacy and limited systemic exposure and toxicity. In the latter part of the 1990s, several large international trials were initiated to evaluate the effect on inhaled corticosteroids in COPD. Unfortunately, the results of these major clinical trials failed to demonstrate any benefit from chronic treatment with inhaled corticosteroids in modifying long-term decline in lung function that is characteristic of COPD. Therefore, the role of inhaled corticosteroids in COPD continues to be debated in the literature, unlike in asthma, where their use is clearly advocated. Much of the debate centers on the appropriate outcome measures in this population of patients.

During the last decade, several studies of inhaled corticosteroids in COPD were designed to detect a benefit on slowing the progressive loss of lung function, but the results were disappointing.[101–106] None of the large national or international trials were able to demonstrate a benefit of high-dose inhaled corticosteroid therapy on this primary outcome. However, inhaled corticosteroids have been associated with other important benefits in some patients, including a decrease in exacerbation frequency and improvements in overall health status.[102,106,107] Clinicians continue to debate the most appropriate and relevant outcome measure to evaluate in COPD studies. Based on the results of clinical trials, consensus guidelines suggest that inhaled corticosteroid therapy should be considered for symptomatic patients with stage III or IV disease (FEV_1<50%) who experience repeated exacerbations.[1,2] These are the patients who demonstrated benefit in clinical trials and in whom a trial of inhaled corticosteroid therapy is warranted. There are also data from epidemiologic studies that suggest that chronic treatment with inhaled corticosteroids is associated with a lower risk of rehospitalization for a broader group of patients with COPD. Thus the debate about the appropriate role for this antiinflammatory therapy continues.

A metaanalysis evaluating randomized clinical trials involving inhaled corticosteroids for patients with COPD indicated that

treatment was associated with a relative risk reduction in exacerbation frequency of 33%. The report indicated that 12 patients would require treatment for 20.8 months to prevent one exacerbation episode. The benefit was evident for patients with moderate to severe COPD.[108] This metaanalysis did not detect a mortality benefit.

Other investigators have reported a reduction in mortality for patients with COPD who were treated with inhaled corticosteroids. In an epidemiologic study of a Canadian database, patient mortality 3 months to 1 year following a hospitalization for a COPD exacerbation was evaluated for patients who received inhaled corticosteroids in the first 3 months compared with those who did not. For patients over 65 years of age, inhaled corticosteroid therapy reduced mortality by 25%. Much of the mortality reduction was reflected in deaths due to cardiovascular causes. Conversely, patients who received only bronchodilator therapy trended toward higher mortality rates, although not significant.[109] A pooled analysis of seven large trials also concluded that inhaled corticosteroids reduced all-cause mortality in COPD patients.[110]

Currently, the recommended role of inhaled corticosteroid therapy is for COPD patients with moderate to severe airflow obstruction (FEV_1 <50% predicted) and who experience frequent exacerbations despite bronchodilator therapy. Repeated exacerbations are described as 3 in 3 years. The initial hope that treatment with inhaled corticosteroids would prevent or slow the progressive decline in FEV_1 remains unproven; however, it is often argued that additional important outcomes for patients with COPD include relief of symptoms, fewer and less severe exacerbations, and improved quality of life.[111] Inhaled corticosteroids (ICs) do not prolong survival in COPD patients and there is good evidence to suggest that treatment with ICs increases the risk of pneumonia for patients with COPD.[112–114]

Although a dose-response relationship for ICs has not been demonstrated in COPD, the major clinical trials employed moderate to high doses for treatment. Side effects of ICs are relatively mild compared with the toxicity from systemic therapy. Hoarseness, sore throat, oral candidiasis, and skin bruising have been reported in the clinical trials. Severe side effects, such as adrenal suppression, osteoporosis, and cataract formation, have been reported less frequently than with systemic corticosteroids, but clinicians should monitor patients who are receiving high-dose chronic therapy.[115,116]

There is evidence supporting a dose relationship between inhaled corticosteroid use and the risk of fractures. In a cohort of over 1,600 subjects with a diagnosis of asthma or COPD (mean age 80 years), the risk of a fracture was 2.53 times higher (CI, 1.65-3.89) in those receiving a mean daily dose of inhaled corticosteroid of 601 mcg or greater.[117] However, the data are conflicting about this issue. A metaanalysis found no evidence supporting an increased risk of fractures or decreased bone mineral density with chronic inhaled corticosteroid use.[118] It appears prudent to suggest that, to minimize the risk of fracture, patients should be treated with the lowest effective dose of ICs.[119] It may also be helpful to recommend adequate intake of calcium and vitamin D and possibly periodic bone mineral density testing.

Combination Therapy: Bronchodilators and Inhaled Corticosteroids

Following the disappointing results of chronic inhaled corticosteroid studies and the progressive decline in lung function, investigators became interested in the combination of potent antiinflammatory therapies and long-acting bronchodilators. Subsequently, several studies have shown an additive benefit with long-acting bronchodilators.[120–123] In various studies, combination therapy with salmeterol plus fluticasone or formoterol plus budesonide was associated with greater improvements in clinical outcomes such as FEV_1, health status, and frequency of exacerbations compared with ICs or long-acting bronchodilators alone. The availability of combination inhalers (e.g., salmeterol plus fluticasone and budesonide plus formoterol) makes administration of both ICs and long-acting bronchodilators more convenient for patients and decreases the total number of inhalations needed daily. An inhaled corticosteroid combined with a long acting β-agonist is superior to the individual components in reducing exacerbations, improving lung function and overall health status.[112] Therefore, there is growing evidence that inhaled corticosteroid and long-acting β-agonist combinations improve lung function, as well as reduce symptoms of dyspnea and exacerbation frequency.[122–124]

The combination of a long-acting β-agonist and inhaled corticosteroid has been compared with the long-acting β-agonist therapy alone. In a study involving nearly 1,000 patients with severe but stable COPD, subjects received either salmeterol 50 mcg/fluticasone 500 mcg twice daily or salmeterol 50 mcg twice daily for 44 weeks. Exacerbation frequency was significantly lower in the combination group (334 vs 464 episodes), which corresponded to a 35% reduction in the annualized rate. The time to the first exacerbation was also delayed with the combination therapy.[125] One finding of concern reported in this trial was the increased number of pneumonia cases for patients receiving combination therapy compared with salmeterol alone. There were 23 cases reported compared with 7 in the salmeterol group.[125] An increase in the risk for pneumonia was also reported in the Towards a Revolution in COPD Health (TORCH) study described below.[112]

The largest prospective study to date is referred to as the Towards a Revolution in COPD Health (TORCH) study.[112] This trial consisted of 6,112 patients who received one of four treatments for three years. Treatment groups were placebo, salmeterol 50 mcg twice daily, fluticasone 500 mcg twice daily, or the combination of salmeterol and fluticasone in a single inhaler. The primary outcome was death from any cause and secondary outcomes were exacerbation rates, lung function, and health status. None of the active treatments differed significantly from placebo, although the combination of salmeterol and fluticasone trended toward fewer deaths (P = .052). The combination also reduced exacerbation rates, and improved lung function and health status compared with the other treatments. Exacerbation rates were also significantly reduced with combination therapy compared with either single agent alone. Both treatment groups that included fluticasone had higher rates of pneumonia. Although this study did not reflect a mortality benefit, the authors indicated the risk of death was reduced by 17.5% with the combination and that the number needed to treat for 1 year to provide a benefit was 4.

For patients with an FEV_1 of less than 60% predicted, the individual agents and the combination decreased the rate of spirometry decline.[58]

In a head-to-head trial, a large study comparing a combination of salmeterol and fluticasone to tiotropium alone showed no difference in the exacerbation rates between the groups, although the combination therapy was associated with a higher study completion rate.[126]

Combinations of Long-Acting Bronchodilators Compared with Long-Acting Bronchodilators Plus Inhaled Corticosteroids The combination of salmeterol and tiotropium has also been evaluated in a short-term crossover study involving only 22 subjects who received either salmeterol (50 mcg twice daily) plus fluticasone (500 mcg twice daily), fluticasone plus tiotropium (18 mcg once daily), or fluticasone, salmeterol, and tiotropium for 1 week. The triple combination provided a significant benefit of improved lung function compared with either of the dual treatments in subjects with moderate to severe COPD.[127] The benefit of

triple therapy was evaluated in a 1 year randomized, double-blind, placebo control study involving 449 subjects with moderate to severe COPD. Treatment consisted of either tiotropium, tiotropium plus salmeterol, or tiotropium, salmeterol, and fluticasone.[128] There was no difference between treatments for the primary outcome of percentage of patients experiencing an exacerbation requiring systemic corticosteroids or antibiotics. The triple-drug regimen improved lung function, quality of life, and reduced hospitalization compared with tiotropium alone, while two-drug therapy did not offer any benefit in lung function improvement or hospitalization rates compared with the single agent. Another small study evaluated the addition of tiotropium for 1 month to a regimen of an inhaled corticosteroid and a long-acting β-agonist.[129] The addition of tiotropium improved lung function and quality-of-life scores, apparently by improving dynamics of lung capacity (inspiratory capacity). These effects were reversed when tiotropium therapy was discontinued. These data involving combinations of long acting bronchodilators are limited and preliminary. More research is required and should include other outcome parameters including relief of symptoms, exacerbation rates, and quality of life. Larger sample sizes and longer durations will provide insight into the value of combinations.

A retrospective cohort study of 42,090 patients in the Veterans Affairs healthcare system evaluated outcomes for patients with COPD who received tiotropium as part of a COPD regimen compared with a cohort of COPD patients who did not receive the medication. Patients who received tiotropium with ICs plus a long-acting β-agonist exhibited a 40% reduction in mortality compared with patients treated with ICs plus a long-acting β-agonist alone (95% CI of 0.45-0.79). Triple therapy patients also significantly reduced exacerbations and hospitalization rates. However, this same study demonstrated that tiotropium combined with two other medications (various) increased mortality and morbitity risks.[85]

α_1-Antitrypsin Replacement Therapy

For patients with inherited AAT deficiency-associated emphysema, treatment focuses on reduction of risk factors such as smoking, symptomatic treatment with bronchodilators, and augmentation therapy with replacement AAT. Based on knowledge about the relationship between serum concentrations of AAT and the risk of developing emphysema, the rationale for augmentation therapy is to maintain serum concentrations above the protective threshold throughout the dosing interval.[130] Indirect evidence of AAT activity in the interstitium of the lung has been demonstrated by measuring concentrations of the enzyme in epithelial lining fluid obtained during bronchoalveolar lavage. Augmentation therapy consists of weekly infusions of pooled human AAT to maintain AAT plasma levels over 10 micromolar. Much of the data supporting the use of AAT replacement is based on evidence of biochemical efficacy (e.g., administering the product and demonstrating protective serum concentrations of AAT).

Clinical evidence for slowing lung function decline or improving outcomes with augmentation therapy is sparse. Stated challenges to performing randomized clinical trials include the large sample size and long duration of follow-up required, and the expense of conducting such a trial. One observational study followed patients in the National Registry of Severe AAT Deficiency over a period of several years and documented clinical outcomes. In this study, patients who received weekly augmentation therapy with purified AAT had slower declines in FEV_1 and decreased mortality compared with patients who never received augmentation therapy.[131] However, this was an observational study of patients, not a randomized, placebo-controlled trial, and so direct cause-and-effect relationships cannot be concluded. One randomized, placebo-controlled study of patients with severe AAT deficiency (ZZ phenotype) did show a significant reduction in lung tissue loss and destruction as measured by computed tomographic (CT) scan for patients receiving augmentation therapy.[132] Other measures of lung function and mortality were not recorded.

The recommended dosing regimen for replacement AAT is 60 mg/kg administered intravenously once a week at a rate of 0.08 mL/kg per minute, adjusted to patient tolerance. It has been estimated that this form of augmentation therapy will cost over $54,000 annually.[133] In the absence of alternative treatments, it is difficult to assess the cost-effectiveness using conventional criteria. There have been repeated problems with supply of this biologic replacement therapy (derived from pooled blood donors) related to production difficulty and contamination issues. Currently, there are three products available (Prolastin (Bayer), Aralast (Baxter), and Zemaira (ZLB Behring), which should minimize this problem in the future. Drug development research continues in the area of recombinant products and inhalational therapy.

The safety of AAT replacement therapy has been recently evaluated in two large observational studies. In the most recent study, 174 patients (n = 747) reported 720 adverse events, classified as severe in 8.8% of cases and moderate in 72.4% of cases.[134] Common complaints included headache, dizziness, nausea, dyspnea, and fever. The overall rate of adverse events was low (i.e., two events over 5 years).

TREATMENT

COPD Exacerbation

DESIRED OUTCOMES

⑩ The goals of therapy for patients experiencing exacerbations of COPD are (1) prevention of hospitalization or reduction in hospital stay, (2) prevention of acute respiratory failure and death, and (3) resolution of exacerbation symptoms and a return to baseline clinical status and quality of life.[135] Acute exacerbations can range from mild to severe. Factors that influence the severity, and subsequently the level of care required, include the severity of airflow limitation, presence of comorbidities and the history of previous exacerbations. Table 34–12 includes factors that warrant treatment in the hospital.

Various therapeutic options for exacerbation management are summarized in Table 34–13. Pharmacotherapy consists of intensification of bronchodilator therapy and a short course of systemic corticosteroids. Antimicrobial therapy is indicated in the presence of selected symptoms. Since the frequency and severity of exacerbations are closely related to each patient's overall health status, all patients should receive optimal chronic treatment, including smoking cessation, appropriate pharmacologic therapy, and preventative therapy such as vaccinations.

TABLE 34-12 Factors Favoring Hospitalization for Treatment of COPD Exacerbation

Presence of high risk comorbidity (e.g., pneumonia, arrhythmia, CHF, diabetes, renal or hepatic failure)
Suboptimal response to outpatient management
Marked worsening of dyspnea
Inability to eat or sleep due to symptoms
Worsening hypoxemia or hypercapnia
Mental status changes
Lack of home support for care
Uncertain diagnosis

Modified from ATS.

TABLE 34-13 Therapeutic Options for Acute Exacerbations of COPD

Therapy	Comments
Antibiotics	Recommended if two or more of the following are present: Increased dyspnea Increased sputum production Increased sputum purulence
Corticosteroids	Oral or intravenous therapy may be used. If intravenous is used, it should be changed to oral after improvement in pulmonary status. If continued longer than 14 days, then the dose should be tapered to avoid HPA Axis suppression.
Bronchodilators	MDIs and DPIs equal in efficacy to nebulization. β-Agonists also may increase mucociliary clearance. Long-acting β-agonists should not be used for quick relief of symptoms or on an as-needed basis.
Controlled oxygen therapy	Titrate oxygen to desired oxygen saturation (>90%). Monitor arterial blood gas for development of hypercapnia.
Noninvasive mechanical ventilation	Consider for patients with acute respiratory failure. Not appropriate for patients with altered mental status, severe acidosis, respiratory arrest, or cardiovascular instability.

NONPHARMACOLOGIC THERAPY

Controlled Oxygen Therapy

Oxygen therapy should be considered for any patient with hypoxemia during an exacerbation. Caution must be used, however, because many patients with COPD rely on mild hypoxemia to trigger their drive to breathe. In normal, healthy individuals, the drive to breathe is triggered by carbon dioxide accumulation. For patients with COPD who retain carbon dioxide as a result of their disease progression, hypoxemia rather than hypercapnia becomes the main trigger for their respiratory drive. Overly aggressive administration of oxygen to patients with chronic hypercapnia may result in respiratory depression and respiratory failure. Oxygen therapy should be used to achieve a Pao_2 of greater than 60 mm Hg or oxygen saturation of greater than 90%. However, an ABG should be obtained after oxygen initiation to monitor carbon dioxide retention owing to hypoventilation.

Noninvasive Mechanical Ventilation

Noninvasive positive-pressure ventilation (NPPV) provides ventilatory support with oxygen and pressurized airflow using a face or nasal mask with a tight seal but without endotracheal intubation. There have been numerous trials reporting the benefits of NPPV for patients with acute respiratory failure due to COPD exacerbations. In one metaanalysis of eight studies, NPPV was associated with lower mortality, lower intubation rates, shorter hospital stays, and greater improvements in serum pH in 1 hour compared with treatment with usual care alone.[136] The benefits seen with NPPV generally can be attributed to a reduction in the complications that often arise with invasive mechanical ventilation. Not all patients with COPD exacerbations are appropriate candidates for NPPV. Patients with altered mental status may not be able to protect their airway and thus may be at increased risk for aspiration. Patients with severe acidosis (pH <7.25), respiratory arrest, or cardiovascular instability should be not considered for NPPV. Patients failing a trial of NPPV or those considered poor candidates might be considered for intubation and mechanical ventilation.

PHARMACOLOGIC THERAPY

Bronchodilators

During exacerbations, intensification of bronchodilator regimens is used commonly. The doses and frequency of bronchodilators are increased to provide symptomatic relief. Short-acting β_2-agonists are preferred owing to rapid onset of action. Anticholinergic agents may be added if symptoms persist despite increased doses of β_2-agonists. In fact, combinations of these agents are employed often, although data are lacking about the benefit versus higher doses of one agent. Bronchodilators may be administered via MDIs or nebulization with equal efficacy. Nebulization may be considered for patients with severe dyspnea who are unable to hold their breath after actuation of an MDI. Clinical evidence supporting the use of theophylline during exacerbations is lacking, and thus theophylline generally should be avoided. However, addition of one of these agents may be considered for patients not responding to other therapies. The risk of adverse effects such as cardiac arrhythmias should be considered and serum levels monitored closely.

Corticosteroids

Until recently, the literature supporting the use of corticosteroids in acute exacerbations of COPD was sparse. However, since 1996, five studies have been performed that document the value of systemic corticosteroids in exacerbations of COPD.[137–141] The Systemic Corticosteroids in Chronic Obstructive Pulmonary Disease Exacerbations (SCCOPE) trial evaluated three groups of patients hospitalized for exacerbations of COPD.[137] The first group received an 8-week course of corticosteroids given as methylprednisolone 125 mg intravenously every 6 hours for 72 hours, followed by once-daily oral prednisone (60 mg on days 4 through 7, 40 mg on days 8 through 11, 20 mg on days 12 through 43, 10 mg on days 44 through 50, and 5 mg on days 51 through 57). The second group received a 2-week course given as methylprednisolone 125 mg intravenously every 6 hours for 72 hours, followed by oral prednisone (60 mg on days 5 through 7, 40 mg on days 8 through 11, and 20 mg on days 12 through 15) and placebo on days 16 through 57. The third group received placebo for all 57 days of study. Rates of treatment failure and hospital stay were significantly higher in the placebo group than in either treatment group at 30 and 90 days. Groups randomized to corticosteroid treatment also had a significantly shorter length of hospital stay compared with the placebo group. The 8-week regimen was not found to be superior to the 2-week regimen. Significant treatment benefits were no longer evident at 6 months.

Davies and colleagues[138] evaluated the oral use of corticosteroids in hospitalized patients with acute exacerbations of COPD. Patients received either 30 mg/day oral prednisolone or placebo for 14 days. Patients who were treated with corticosteroids had a significantly more rapid improvement in FEV_1 and a shorter hospital stay than did patients who received placebo. There was no significant difference between groups at 6-week follow-up.

In total, results from these trials suggest that patients with acute exacerbations of COPD should receive a short course of intravenous or oral corticosteroids. However, because of the large variability in dosage ranges, the optimal dose and duration of corticosteroid treatment are not known. It appears that short courses (9 to 14 days) are as effective as longer courses and have a lower risk of associated adverse effects owing to less time of exposure. Several trials used high initial doses of steroids before tapering to a lower maintenance dose. Adverse effects such as hyperglycemia, insomnia, and hallucinations may occur at higher doses. Depending on the clinical status of the patient, treatment may be initiated at a

lower dose or tapered more quickly if these effects occur. It appears that a regimen of prednisone 40 mg orally daily (or equivalent) for 10 to 14 days can be effective for most patients.[142] If steroid treatment is continued for greater than 2 weeks, a tapering oral schedule should be employed to avoid hypothalamic-pituitary-adrenal (HPA) axis suppression.

Recent data suggest that ICs may be beneficial for treating COPD exacerbations, although this is not the standard of care. In one study, inhaled budesonide, alone or combined with formoterol, was as effective as oral corticosteroids in treating COPD exacerbations.[143]

Antimicrobial Therapy

11 It is thought that most acute exacerbations of COPD are caused by viral or bacterial infections. However, as many as 30% of exacerbations are caused by unknown factors.[1] A metaanalysis of nine studies evaluating the effectiveness of antibiotics in treating exacerbations of COPD determined that patients receiving antibiotics had a greater improvement in peak expiratory flow rate than those who did not.[144]

This metaanalysis concluded that antibiotics are of most benefit and should be initiated if at least two of the following three symptoms are present: increased dyspnea, increased sputum volume, and increased sputum purulence. The utility of sputum Gram stain and culture is questionable because some patients have chronic bacterial colonization of the bronchial tree between exacerbations.

The emergence of drug-resistant organisms has mandated that antibiotic regimens be chosen judiciously. Selection of empirical antimicrobial therapy should be based on the most likely organism(s) thought to be responsible for the infection based on the individual patient profile. The most common organisms for any acute exacerbation of COPD are *Hemophilus influenzae, Moraxella catarrhalis, Streptococcus pneumoniae,* and *Hemophilus parainfluenzae.* More virulent bacteria may be present for patients with more complicated acute exacerbations of COPD, including drug-resistant pneumococci, β-lactamase-producing *H. influenzae* and *M. catarrhalis,* and enteric gram-negative organisms, including *Pseudomonas aeruginosa.* Table 34–14 summarizes recommended antimicrobial therapy for exacerbations of COPD and the most common organisms based on patient presentation.[145]

Therapy with antibiotics generally should be continued for at least 7 to 10 days. Studies evaluating shorter treatment courses (usually 5 days) with the fluoroquinolones, second- and third-generation cephalosporins, and macrolide antimicrobials have demonstrated comparable efficacy with the longer treatment regimens.[146] If the patient deteriorates or does not improve as anticipated, hospitalization may be necessary, and more aggressive attempts should be made to identify potential pathogens responsible for the exacerbation.

COPD patients are at increased risk for pulmonary embolism during severe exacerbations requiring hospitalizations. An increased awareness of this risk and appropriate preventative measures are warranted.[147]

COMPLICATIONS

Cor Pulmonale

Cor pulmonale is right-sided heart failure secondary to pulmonary hypertension. Long-term oxygen therapy and diuretics have been the mainstays of therapy for cor pulmonale. Increasing the Pao_2 above 60 mm Hg with supplemental oxygen therapy decreases pulmonary hypertension and thus decreases the force against which the right ventricle has to work. While diuretics may help decrease fluid overload, caution should be used because patients with significant right-sided heart failure are highly dependent on preload for cardiac output. Therefore, the decision to use diuretics must be based on a risk-to-benefit ratio. Digitalis glycosides have no role in the treatment of cor pulmonale.

Other pharmacologic agents that have been investigated to treat cor pulmonale include hydralazine, calcium channel blockers, angiotensin-converting enzyme inhibitors, and angiotensin II antagonists. However, there is insufficient evidence to offer guidelines for the role of these agents in COPD patients with cor pulmonale.

Polycythemia

Polycythemia secondary to chronic hypoxemia in COPD patients can be improved by either oxygen therapy or periodic phlebotomy if oxygen therapy alone is not sufficient. COT was shown by the Nocturnal Oxygen Therapy Trial Group to reduce hematocrit values in treated patients.[31] Acute phlebotomy is indicated if the hematocrit is above 55% to 60% and the patient is experiencing central nervous system effects suggestive of sludging from high blood viscosity. Long-term oxygen then can be used to maintain a lower hematocrit.

TABLE 34-14 Recommended Antimicrobial Therapy in Acute Exacerbations of COPD

Patient Characteristics	Likely Pathogens	Recommended Therapy
Uncomplicated exacerbations <4 exacerbations per year No comorbid illness FEV_1 >50% of predicted	*S. pneumoniae* *H. influenzae* *M. catarrhalis* *H. parainfluenzae* Resistance uncommon	Macrolide (azithromycin, clarithromycin) Second- or third-generation cephalosporin Doxycycline Therapies not recommended[a]: TMP/SMX, amoxicillin, first-generation cephalosporins, and erythromycin
Complicated exacerbations: Age ≥ 65 and >4 exacerbations per year FEV_1 <50% but >35% of predicted	As above plus drug-resistant pneumococci, β-lactamase–producing *H. influenzae* and *M. catarrhalis*	Amoxicillin/clavulanate Fluoroquinolone with enhanced pneumococcal activity (levofloxacin, gemifloxacin, moxifloxacin)
Complicated exacerbations with risk of *P. aeruginosa* Chronic bronchial sepsis[b] Need for chronic corticosteroid therapy Resident of nursing home with <4 exacerbations per year FEV_1 <35% of predicted	Some enteric gram-negatives As above plus *P. aeruginosa*	Fluoroquinolone with enhanced pneumococcal and *P. aeruginosa* activity (levofloxacin) IV therapy if required: β-lactamase resistant penicillin with antipseudomonal activity 3rd- or 4th-generation cephalosporin with antipseudomonal activity

[a]TMP/SMX should not be used due to increasing pneumococcal resistance; amoxicillin and first-generation cephalosporins are not recommended due to β-lactamase susceptibility; and erythromycin is not recommended due to insufficient activity against *H. influenzae*.
[b]In sepsis, double antipseudomonal coverage should be considered (e.g., addition of aminoglycoside).
Modified and updated from reference 1.

OTHER PHARMACOLOGIC CONSIDERATIONS

A number of other treatments have been explored over the years. Among these therapies, either there is insufficient evidence to warrant recommending their use or they have been proven to not be beneficial in the management of COPD. A brief summary is provided because the clinician likely will encounter patients who are receiving or inquire about these treatments.

Suppressive Antimicrobial Agents

Because COPD patients often are colonized with bacteria and experience recurrent exacerbations of their condition, a common practice employed in the past has been the use of low-dose antimicrobial therapy as preventative or prophylaxis against these acute exacerbations. However, clinical studies over the past 40 years have failed to demonstrate any benefit from this practice.[1] The role of antimicrobial therapy is limited to acute exacerbations of COPD meeting specific criteria.

Expectorants and Mucolytics

Adequate water intake generally is acceptable to maintain hydration and assist in the removal of airway sections. Beyond this, the regular use of mucolytics or expectorants for COPD patients has no proven benefit.[148] This includes the use of saturated solutions of potassium iodide, ammonium chloride, acetylcysteine, and guaifenesin. In 2007, the FDA announced its intention to take action against several companies marketing unapproved timed-released formulations of guaifenesin. Two formulations are approved by the FDA (Humibid and Mucinex); however, data are lacking on their benefit.

Narcotics

Systemic (oral and parenteral) opioids, especially morphine, can relieve dyspnea for patients with end-stage COPD. Nebulized therapy is sometimes used in clinical practice although data about clinical benefit are lacking.[149] Opioids should be used carefully, if at all, to avoid adverse effects on ventilatory drive.

Respiratory Stimulants

There is no role for respiratory stimulants in the long-term management of COPD.[1] Agents that have shown some utility in the acute setting include almitrine and doxapram. However, almitrine is available only in Europe, and its usefulness is limited by neurotoxicity. Doxapram is available for intravenous use only and may be no better than intermittent NPPV.

Secondary pulmonary hypertension is a feature of severe COPD. This has prompted interest about the potential role of agents used to treat primary pulmonary hypertension. However, the use of an endothelin receptor antagonist (bosentan) failed to improve exercise tolerance and worsened hypoxemia in one trial.[150]

SURGICAL INTERVENTION

Various surgical options have been employed in the management of COPD. These include bullectomy, lung volume reduction surgery (LVRS), and lung transplantation. Bullectomy has been performed for many years and may be useful when large bullae (>1 cm) are noted on computerized axial tomography (CT or CAT) scan. The presence of bullae may contribute to complaints of dyspnea, and their removal can improve lung function and reduce symptoms, although there is no evidence of a mortality benefit. Because of the prevalence of COPD, it is the most frequent indication for lung transplantation. Intervention is considered when predicted survival is less than 2 years, FEV_1 is <25% predicted, and hypoxemia, hypercapnia, and pulmonary hypertension exists despite medical management.[2] Experience to date shows 2-year survival of 655 to 90%, and 5-year survival of 415 to 53%.

Recent trials have evaluated the effect of bilateral lung volume reduction surgery (LVRS) for management of severe COPD. Short-term trials comparing the effects of pulmonary rehabilitation plus LVRS with pulmonary rehabilitation alone reported that the combination of treatments resulted in greater improvements in lung function, gas exchange, and quality of life at 3 months. Only recently have data evaluating the long-term effect of LVRS compared with pulmonary rehabilitation been published. The National Emphysema Treatment Trial (NETT), a prospective, randomized trial evaluating the long-term effects of LVRS plus pulmonary rehabilitation compared with pulmonary rehabilitation alone, followed 1,218 patients for 3 years.[151] The primary end points for the study were mortality and maximal exercise capacity 2 years after randomization. Secondary end points included pulmonary function, distance walked in 6 minutes, and quality-of-life measurements. At an interim analysis, patients with an FEV_1 of less than 20% of predicted or a carbon monoxide diffusing capacity of less than 20% of predicted were noted to be at high risk of death after surgery and subsequently were excluded from the study. Results of the study showed no mortality benefit with LVRS compared with pulmonary rehabilitation alone. Patients undergoing surgery had improved exercise capacity, lung function, and quality of life at 2 years, but these patients also had a higher risk of short-term morbidity and mortality associated with the surgery. A subgroup analysis of the study noted that patients with predominately upper-lobe emphysema and low exercise capacity undergoing surgery had lower mortality rates at 2 years compared with patients treated with medical therapy alone. Because of the costs and risks associated with LVRS, more studies are needed to better determine the ideal surgical candidates and identify subgroups of patients that would benefit most from surgery. The long-term benefits of LVRS are exhibited as improved Po_2 and decreased requirements for supplemental oxygen during treadmill walking as well as self-reported oxygen requirements for up to 24 months after the procedure.[152]

DIETARY SUPPLEMENTS

There has been increasing interest in the role of antioxidants, including vitamins E and C and β-carotene, in reducing the frequency of exacerbations. It is postulated that they may be beneficial in COPD as a result of an imbalance between oxidants and antioxidants that has been considered in the pathogenesis of smoking-induced lung disease. However, there is no good evidence that antioxidant therapies improve COPD symptoms or slow disease progression. Nutritional supplements, including creatine, have not proven beneficial to improve the benefit of pulmonary rehabilitation programs.[153]

INVESTIGATIONAL THERAPIES

Based on the knowledge about the importance of neutrophilic inflammation in COPD and potential therapeutic benefit of inhibition of neutrophil activity, a number of antiinflammatory compounds are being explored. Specifically, agents inhibiting leukotriene B_4, neutrophil elastase, and phosphodiesterases currently are being evaluated. To date, studies evaluating leukotriene-modifying therapies have been disappointing. Further studies are needed to evaluate the clinical benefit of such inhibitors for patients with COPD.

Phosphodiesterase 4 (PDE4) is the major phosphodiesterase found in airway smooth muscle cells and inflammatory cells and

is responsible for degrading cAMP. Inhibition of PDE4 results in relaxation of airway smooth muscle cells and decreased activity of inflammatory cells and mediators such as TNF-α and IL-8. Two PDE4 inhibitors, cilomilast and roflumilast, have reached clinical trials. Cilomilast has been evaluated in several human trials and has been shown to improve expiratory airflow as measured by FEV_1 for patients with COPD when given at a dose of 15 mg twice daily for 6 weeks. To date, the results of clinical trials investigating these agents have been modest. Future studies of these agents should evaluate effects on other clinical outcomes such as health status, exacerbation frequency, and progression of disease.

Neutrophil elastase is implicated in the induction of bronchial disease, causing structural changes in lungs, impairment of mucociliary clearance, and impairment of host defenses. Protease inhibitors, namely, inhibitors of neutrophil elastase, are being investigated currently for the treatment of COPD.

Results have been disappointing in evaluating the benefit of infliximab, a tumor necrosis factor α-blocker, in treating COPD. A total of 234 patients with moderate to severe COPD received either infliximab 3 mg/kg or 5 mg/kg or placebo at baseline, 2, 6, 12, 18, and 24 weeks. Subjects completed a quality-of-life questionnaire [Chronic Respiratory Questionnaire (CRQ)] during treatment and out to 44 weeks. There were no differences on the CRQ or on any secondary end points including lung function, exercise capacity, or exacerbation rates. The discontinuation rate due to adverse events was high (20–27%) in the active treatment group.[154]

PHARMACOECONOMIC CONSIDERATIONS

The overall cost of therapy is an important consideration in contemporary medical practice. Meaningful cost analysis goes beyond the cost of the medication itself and incorporates the impact of a given therapeutic agent on overall healthcare cost. Because of the relative lack of benefit among objective outcome measures in COPD clinical trials, pharmacoeconomic studies can be useful in decision making about pharmacotherapy options. Pharmacoeconomic analyses in COPD, although limited, are available regarding antibiotic use in acute exacerbations and some therapies for management of chronic stable COPD.

The costs of managing an acute exacerbation of COPD in the ambulatory setting was evaluated in over 2,400 patients. Subjects were followed for 1 month following the diagnosis of the exacerbation. The overall relapse rate was 21%, with 31% and 16% of subjects requiring care in the emergency department and hospital, respectively. The overall costs for exacerbation treatment averaged $159, with 58% attributed to hospitalization.[155] These authors concluded that a significant cost savings would result from improving the successful ambulatory management of acute exacerbations.

Grossman and colleagues conducted a trial investigating the use of aggressive antimicrobial therapy (ciprofloxacin) compared with usual antibiotic therapy (defined as any nonquinolone) in the treatment of acute exacerbations of COPD.[156] Overall, the results indicated no preference for either treatment arm. However, for patients who were categorized as high risk (severe underlying lung disease, more than four exacerbations per year, duration of bronchitis greater than 10 years, elderly, significant comorbid illness), the use of aggressive antibiotic therapy was associated with improved clinical outcome, higher quality of life, and fewer costs. The results of this study are consistent with Table 34–14, which suggests that higher-risk patients are likely to have more resistant strains of organisms and thus require more aggressive antimicrobial treatment.

Few data are available about the cost-effectiveness of educational programs for patients with COPD. In an outpatient clinic, patients attending one 4-hour group session, followed by one to two individual sessions with a clinician, reported improved outcomes, and costs were reduced in an evaluation 12 months later.[157] Additional research is needed regarding the best model for education and also the specific self-management strategies to teach.

Friedman and colleagues conducted a post hoc pharmacoeconomic evaluation of two multicenter, randomized trials comparing the combination of ipratropium and albuterol with both drugs used as monotherapy.[158] Patients who received a combination of ipratropium and albuterol had lower rates of exacerbations, lower overall treatment costs, and improved cost-effectiveness compared with either drug used alone. With the introduction of new bronchodilator therapies and with no clearly consistent advantage of one class of agents over another, pharmacoeconomic analyses may be useful for clinicians in determining the most appropriate therapy for their patients.

CLINICAL CONTROVERSIES

In the United States, all products containing a LABA agent, either alone or in combination with ICs, include a black box warning about an increased risk of severe asthma attacks or death associated with their use. This caution applies to patients with asthma, and it is strongly recommended that LABAs use should always be in conjunction with another controller therapy (e.g., ICs) and that use should be limited in duration. This concern only applies to patients with asthma and is not relevant concerning the use of LABA therapy for COPD patients.

A combination product of a long-acting inhaled β-agonist (salmeterol) and an inhaled corticosteroid agent (fluticasone) is one of the most commonly prescribed medications for lung disease, including COPD. However, in expert guidelines, ICs are indicated only for patients with more severe disease who experience frequent exacerbations. Many patients now receiving therapy with the combination inhaler may be candidates for bronchodilator therapy alone, although the benefit of ICs continues to be a focus of clinical research, including the potential for a mortality benefit.

The role of systemic corticosteroids for acute exacerbations of COPD has been clarified in recent years. However, the appropriate dosage regimen is not well established. Regimens range from initial high doses (methylprednisolone 125 mg every 6 hours) to more conservative dosing (prednisone 40–60 mg/day). Consensus guidelines indicate that bronchodilator therapy is the focus of pharmacotherapy for COPD. However, there is no clear choice for the initial agent. For patients with daily but not persistent symptoms, either ipratropium or albuterol offers advantages as initial therapy. Both also have limitations if chosen as the initial therapy.

International guidelines recommend long-acting bronchodilator therapy for patients with moderate to very severe disease or when symptoms are not adequately managed with short-acting agents or as needed therapy. When response to a single long-acting bronchodilator is not optimal, guidelines recommend the use of combinations. However, data are lacking presently about the therapeutic benefit of combinations of long-acting bronchodilators, and this approach is associated with substantial costs.

EVALUATION OF THERAPEUTIC OUTCOMES

To evaluate therapeutic outcomes of COPD effectively, the practitioner must first delineate between chronic stable COPD and acute exacerbations. In chronic stable COPD, pulmonary function tests should be assessed periodically and with any therapy addition, change in dose, or deletion of therapy. Because objective improvements often are minimal, subjective assessments are important. Other outcome parameters are commonly evaluated, including dyspnea score, quality-of-life assessments, and exacerbation rates, including visits to the emergency department or hospitalization. In acute exacerbations of COPD, white blood cell count, vital signs, chest x-ray, and changes in frequency of dyspnea, sputum volume, and sputum purulence should be assessed at the onset and throughout treatment of an exacerbation. In more severe exacerbations, ABGs and oxygen saturation also should be monitored. As with any drug therapy, patient adherence to therapeutic regimens, side effects, potential drug interactions, and subjective measures of quality of life also must be evaluated.

END-OF-LIFE CARE

Based on the natural course of COPD, characterized by the progressive decline in lung function and development of complications, consideration should be given to end-of-life decisions and advanced directives.[159] Factors associated with expected mortality within 1 year have been identified. These include older age, diagnosis of depression, declining overall health status, hypercapnia, an FEV_1 of less than 30% predicted, ability to walk only a few steps without resting, more than one emergent hospitalization in the past year, and the presence of comorbidities, including congestive heart failure. An effective strategy to discuss end-of-life care involves the patient's participation in identifying advanced directives. Patients should be assured that symptoms, including pain, will be managed and their dignity will be preserved. Specific issues that should be addressed include location and provider for terminal care, desires to use or withhold mechanical ventilation, and involvement of other family members in decisions on behalf of the patient.

ABBREVIATIONS

AAT: α_1-antitrypsin

BMI: body mass index

COPD: chronic obstructive pulmonary disease

D_LCO: diffusion capacity for carbon monoxide

DPI: dry powder inhaler

FEV_1: forced expiratory volume in 1 second

FVC: forced vital capacity

GOLD: Global Initiative for Chronic Obstructive Lung Disease

Hg: mercury

LVRS: lung volume reduction surgery

CHAPTER 35

Pulmonary Arterial Hypertension

REBECCA MOOTE, REBECCA L. ATTRIDGE, AND DEBORAH J. LEVINE

KEY CONCEPTS

1. Pulmonary arterial hypertension (PAH) may be defined as a mean pulmonary artery pressure (mPAP) ≥25 mm Hg at rest with a pulmonary wedge pressure (also known as pulmonary artery occlusion pressure) or left ventricular end diastolic pressure (LVEDP) ≤15 mm Hg measured by right cardiac catheterization.
2. Regardless of the etiology, be it unknown or related to an associated medical condition, subgroups of PAH are based on similar clinical and pathological physiology.
3. Diagnosis of PAH is growing due to increased awareness and knowledge of the disease state, leading to earlier and improved evaluation and identification.
4. The underlying cause of PAH is a complicated amalgam of endothelial cell dysfunction, a procoagulant state, platelet activation, vasoconstriction, loss of relaxing factors, cellular proliferation, hypertrophy, fibrosis, and inflammation.
5. Patients with PAH present with exertional dyspnea, fatigue, weakness, and exertion intolerance. As the disease progresses, symptoms of right heart dysfunction and failure, such as dyspnea at rest, lower extremity edema, chest pain, and syncope, are seen.
6. The only way to make a definitive diagnosis of PAH is by right heart catheterization. The right heart catheterization provides important prognostic information and can be used to assess pulmonary vasoreactivity prior to initiating therapy.
7. The goals of treatment are to alleviate symptoms, improve the quality of life, slow the progression of the disease, and improve survival.
8. A general goal of PAH treatment is to correct the imbalance between vasoconstriction and vasodilation and prevent adverse thrombotic events to improve oxygenation and quality of life.
9. Nonpharmacologic therapy is frequently used to address comorbid conditions that often accompany PAH.
10. Conventional therapy of PAH includes oral anticoagulants, diuretics, oxygen, and digoxin.
11. Prostacyclin analogs such as epoprostenol, treprostinil, and iloprost induce potent vasodilation of pulmonary vascular beds.
12. Endothelin receptor antagonists, bosentan, ambrisentan, and sitaxsentan, improve exercise capacity, hemodynamics, and functional class in PAH.
13. Phosphodiesterase-5 inhibitors, including sildenafil and tadalafil, are potent and highly specific drugs that have been shown to reduce mPAP and improve functional class.
14. Only a very small number of patients with PAH demonstrate a favorable response to acute vasodilator testing. These are the only patients amenable to therapy with calcium channel blocker.
15. Combination therapy in PAH may address more than one mechanism causing this disease. Combination therapy in clinical trials has provided additional benefit but more studies are needed.

The complete chapter, learning objectives, and other resources can be found at **www.pharmacotherapyonline.com**.

1 Pulmonary arterial hypertension (PAH) may be defined as a mean pulmonary artery pressure (mPAP) ≥25 mm Hg at rest, with a pulmonary wedge pressure (also known as pulmonary artery occlusion pressure) or left ventricular end diastolic pressure (LVEDP) ≤15 mm Hg measured by cardiac catheterization.[1] PAH is a disorder that may occur either in the setting of underlying medical conditions or as an idiopathic disease that uniquely affects the pulmonary circulation. Historically, medical treatment of PAH has been problematic due to lack of effective therapy. Idiopathic PAH (IPAH), formerly known as primary pulmonary hypertension, has no known etiology or association with other diseases. Without medical therapy, it portends a poor prognosis (medial survival 2.8 years) after diagnosis.[2] Prior to the availability of disease-specific or targeted drug therapy for IPAH, survival rates for 1, 3, and 5 years were 68%, 48%, and 34%, respectively.[3] Others have found similar survival rates in registry studies.[4,5] Since 1995 when epoprostenol was approved by the FDA, a number of new therapeutic options have been developed. 2 Regardless of the etiology, be it unknown or related to an associated medical condition, all subgroups of PAH are based on similar clinical and pathologic physiology. Several sets of guidelines exist to aid clinicians in diagnosis and management of PAH.[2,6–10]

EPIDEMIOLOGY

3 In 2006, the prevalence of PAH was estimated to be 50,000 to 100,000 individuals in the United States.[7] Unfortunately, only 15,000 to 20,000 of the afflicted patients have an established diagnosis of

PAH and are currently receiving treatment. In a French registry study of more than 600 patients with PAH, Humbert et al. found that the most common cause of PAH was IPAH (approximately 40%), followed by PAH associated with connective tissue diseases (15.3%), congenital heart disease (11.3%), portal hypertension (10.4%), and familial PAH (FPAH) (3.9%).[5] Based on autopsy findings, PAH was found to occur in 0.13% of patients.[8]

ETIOLOGY

PAH most often originates with a predisposing state and one or more inciting stimuli that has been referred to as the "multiple hit hypothesis. Two or more hits may consist of a genetic disorder combined with one or more other genetic or environmental exposures or comorbidities.[11] Once a permissive and provocative environment exists, multiple mechanisms can be activated leading to vascular constriction, cellular proliferation, and a prothrombotic state resulting in PAH and its sequelae.[12] PAH can be associated with numerous conditions (Table 35–1) as well as being an idiopathic condition (IPAH). The World Health Organization classification of PAH defines five groups: pulmonary arterial hypertension, pulmonary hypertension owing to left heart disease, pulmonary hypertension owing to lung diseases and/or hypoxia, chronic thromboembolic pulmonary hypertension (CTEPH), and pulmonary hypertension with unclear multifactorial mechanisms.[10] The incidence of IPAH is estimated to be five to six per 1 million in North America and Europe, with a marked female predominance (male-to-female ratio: 1:1.7) and a mean age at the time of recognition being approximately 37 years but with much variation.[12–15] PAH is a common complication of scleroderma, with 7% to 12% of patients developing PAH. Patients with scleroderma who develop PAH seem to have markedly worse outcomes in comparison with other PAH subgroups. PAH may also be a complication from other connective tissue disorders, including systemic lupus erythematosus, mixed connective tissue disease, and lung fibrosis. Patients with human immunodeficiency virus (HIV) infection can develop PAH with a prevalence of 0.46%. In patients with liver disease, portal hypertension may cause concurrent pulmonary hypertension in an estimated 2% to 6% of patients. Congenital heart diseases may also precipitate development of PAH.[10] Although uncommon in the United States, the most common forms of PAH worldwide are probably schistosomiasis and sickle cell disease followed by congenital heart disease and pulmonary hypertension of early childhood.[16] PAH can be a complication of sickle cell disease and is a major independent risk factor for death. Drugs and toxins that definitively precipitate PAH include anorexic drugs such as aminorex, fenfluramine, and dexfenfluramine.[16–18] Other drugs considered to be likely or possible causative agents for PAH include amphetamines, L-tryptophan, cocaine, and certain chemotherapeutic agents (mitomycin C, carmustine, etoposide, cyclophosphamide, bleomycin).[13,17] Rapeseed oil is also associated with PAH.[13]

TABLE 35-1 World Health Organization Classification of Pulmonary Hypertension

- 1.0 Pulmonary arterial hypertension (PAH)
  - 1.1 Idiopathic (IPAH)
  - 1.2 Heritable
    - 1.2.1 BMPR2
    - 1.2.2 ALK-1, endoglin (with or without hereditary hemorrhagic telangiectasia)
    - 1.2.3 Unknown
  - 1.3 Drug and toxin induced
  - 1.4 Associated with (APAH):
    - 1.4.1 Connective tissue diseases
    - 1.4.2 HIV infection
    - 1.4.3 Portal hypertension
    - 1.4.4 Congenital heart diseases
    - 1.4.5 Schistosomiasis
    - 1.4.6 Chronic hemolytic anemia
  - 1.5 Persistent pulmonary hypertension of the newborn
  - 1.6 Pulmonary veno-occlusive disease (PVOD) and/or pulmonary capillary hemangiomatosis (PCH)
- 2.0 Pulmonary hypertension owing to left-heart disease
  - 2.1 Systolic dysfunction
  - 2.2 Diastolic dysfunction
  - 2.3 Valvular disease
- 3.0 Pulmonary hypertension owing to lung diseases and/or hypoxemia
  - 3.1 Chronic obstructive pulmonary disease
  - 3.2 Interstitial lung disease
  - 3.3 Other pulmonary diseases with mixed restrictive and obstructive pattern
  - 3.4 Sleep-disordered breathing
  - 3.5 Alveolar hypoventilation disorders
  - 3.6 Chronic exposure to high altitude
  - 3.7 Developmental abnormalities
- 4.0 Chronic thromboembolic pulmonary hypertension (CTEPH)
- 5.0 Pulmonary hypertension with unclear multifactorial mechanisms
  - 5.1 Hematologic disorders: myeloproliferative disorders, splenectomy
  - 5.2 Systemic disorders: sarcoidosis, pulmonary Langerhans cell histiocytosis: lymphangioleiomyomatosis, neurofibromatosis, vasculitis
  - 5.3 Metabolic disorders: glycogen storage disease, Gaucher disease, thyroid disorders
  - 5.4 Others: tumoral obstruction, fibrosing mediastinitis, chronic renal failure on dialysis

ALK-1, activin receptor-like kinase type-1; BMPR2, bone morphogenetic protein receptor 2; HIV, human immunodeficiency virus.

Reprinted from J Am Coll Cardiol, Vol. 54, Simonneau G, Robbins IM, Beghetti M, et al. Updated clinical classification of pulmonary hypertension, pages S43–S54, Copyright © 2009, with permission from Elsevier.

Heritable PAH includes both IPAH with germline mutations and familial cases without an identified mutation. Germline mutations seen in PAH include bone morphogenetic protein receptor II (BMPR2) and activin receptor-like kinase type 1 (ALK-1). Mutations in the BMPR2 gene have been identified in approximately 70% of patients with familial PAH and in 11% to 40% of patients with IPAH.[10,19] Genetic testing for BMPR2 and ALK-1 may be offered and professional genetic counseling should be provided.[10]

PATHOPHYSIOLOGY

4 The pathobiology of PAH involves several key biologic events, including endothelial cell dysfunction, a procoagulant state, platelet activation, constricting factors, loss of relaxing factors, cellular proliferation, hypertrophy, fibrosis, and inflammation—all combining to produce progressive and deleterious pulmonary vascular remodeling (Fig. 35–1).[20,21] Genetic substrates that are associated with PAH include BMPR2, ALK-1, nitric oxide synthase (ec-NOS), carbamyl-phosphate synthase gene, and 5-hydroxytryptamine (serotonin) transporter (5-HTT).[12,16,18] A mutation of BMPR2 receptor is an aberration of signal transduction in the pulmonary vascular smooth muscle cell that is postulated to alter apoptosis favoring cellular proliferation. ALK-1 is part of the transforming growth factor-β superfamily and is seen in hereditary hemorrhagic telangiectasia and PAH.[22] 5-HTT is associated with pulmonary artery smooth muscle cell proliferation and is present in IPAH in the homozygous form in 65% of patients.[23] Dysregulation of serotonin (5-HT) synthesis mediated via tryptophan hydroxylases (Tph1 and Tph2) is closely linked to the hypoxic PAH phenotype in mice, and both Tph1 and Tph2 may contribute to PAH development.[24] Known or suspected exposure to HIV infection should be explored.[19]

Molecular and cellular mechanisms are mediated by a variety of biologically active compounds, including prostacyclin (PGI_2), endothelin-1, nitric oxide, and serotonin. PGI_2 is a vasodilatory and

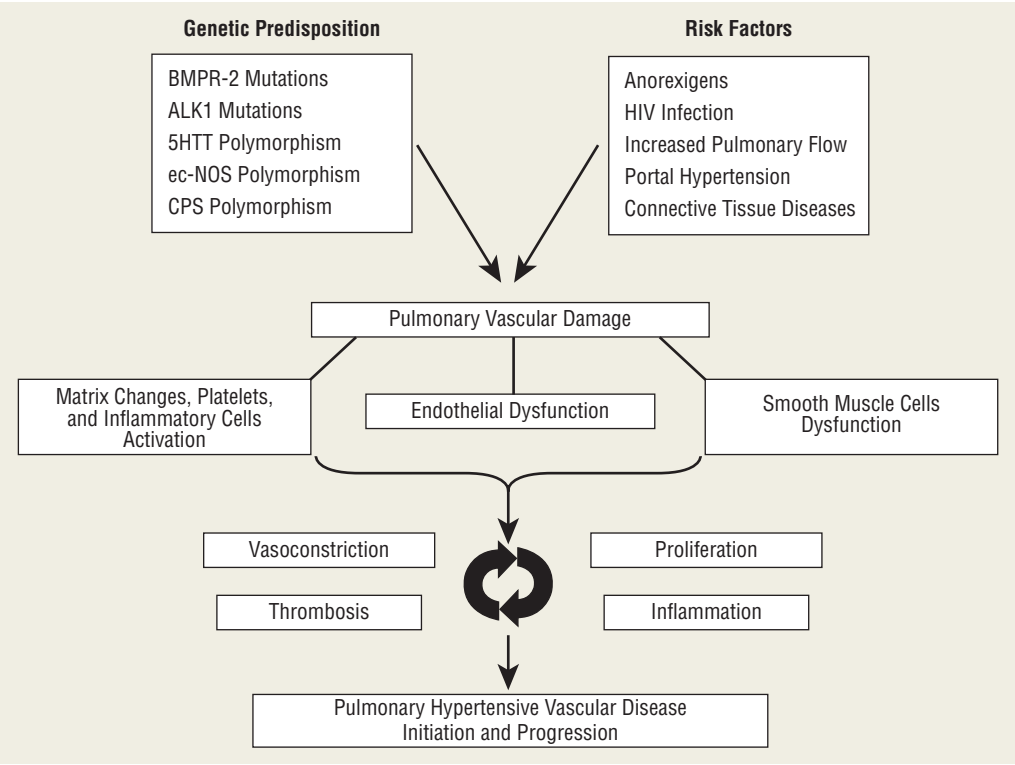

FIGURE 35-1. Pulmonary arterial hypertension; potential pathogenetic and pathobiologic mechanisms. (5-HTT, serotonin transporter gene; ALK-1, activin receptor-like kinase type 1 gene; BMPR-2, bone morphogenetic receptor 2 gene; CPS, carbamyl-phosphate synthase gene; ec-NOS, nitric oxide synthase gene; HIV, human immunodeficiency virus.) *(Reproduced with permission from Galie N, Torbicki A, Barst R. Guidelines on diagnosis and treatment of pulmonary arterial hypertension. Eur Heart J 2004;25:2243–2278.)*

antiproliferative substance that is produced by the endothelial cells, and the synthesis of PGI_2 and its circulating levels are reduced in PAH. Furthermore, thromboxane, a vasoconstrictor, is increased in PAH. Endothelin-1 is produced in the endothelium, and it possesses potent vasoconstrictor and mitogenic effects. Endothelin-1 levels are increased in PAH and clearance is reduced. Endothelin-1 acts via the endothelin receptors (ET_A and ET_B) to promote vascular smooth muscle proliferation and vasoconstriction.[1,20] Plasma levels of endothelin-1 correlate with severity of PAH and prognosis.[25] Nitric oxide (NO) is produced in the endothelium via NO synthase and leads to vasodilation and opening of cell membrane potassium channels to allow potassium ion efflux, membrane depolarization, and calcium channel inhibition. Voltage-dependent potassium channels (Kv 1.5) are inhibited by a number of stimuli that promote PAH, including hypoxia and fenfluramine, resulting in downregulated Kv 1.5 channels in patients with PAH. Entering calcium is a signal for release of sarcoplasmic calcium and activation of the contractile apparatus. NO promotes vasodilation through calcium channel inhibition. In PAH there is evidence of decreased NO synthase expression, leading to vasoconstriction and cell proliferation.[26] Alteration in NO is a therapeutic target, and treatment approaches include inhibition of phosphodiesterase-5 or calcium channel blockade. Elevated 5-HT has been observed and vasoconstriction mediated via the increased expression of the 5- HT_{1B} receptor is seen in PAH.[12]

Autoantibodies, proinflammatory cytokines, and inflammatory infiltrates may also participate in the pathogenesis of PAH. Coagulation is disordered in PAH as evidenced by increased levels of von Willebrand factor, plasma fibrinopeptide A, plasminogen activator inhibitor-1, serotonin, and thromboxane. Furthermore, tissue plasminogen activator, thrombomodulin, NO, and PGI_2 are decreased, leading to an imbalance favoring thrombosis. Endothelial dysfunction is the common denominator of mechanisms for PAH, and a variety of injuries, such as shear stress, inflammation, toxins, and hypoxia, are thought to be involved. In IPAH endothelial dysfunction may occur as a result of proliferation of a monoclonal cell type leading to a plexiform lesion classically associated with this type of PAH. In addition, sleep-disordered breathing and obstructive sleep apnea are associated with cardiovascular morbidity. The reported range of prevalence of PAH in sleep-disordered breathing is 17% to 53%.[27]

5 The signs and symptoms of PAH are highly variable depending on the stage of the disease and comorbidities (Table 35–2). In patients with a clinical suspicion of PAH, Doppler echocardiography should be performed as a noninvasive screening test that can detect increased pulmonary pressures, although it may be imprecise in determining actual pressures compared with cardiac

TABLE 35-2 World Health Organization Functional Classification of Pulmonary Arterial Hypertension (PAH)

Class	Description
I	Patients with PAH in whom there is no limitation of usual physical activity; ordinary physical activity does not cause increased dyspnea, fatigue, chest pain, or presyncope.
II	Patients with PAH who have mild limitation of physical activity. There is no discomfort at rest, but normal physical activity causes increased dyspnea, fatigue, chest pain, or presyncope.
III	Patients with PAH who have marked limitation of physical activity. There is no discomfort at rest, but less than normal physical activity causes increased dyspnea, fatigue, chest pain, or presyncope.
IV	Patients with PAH who are unable to perform any physical activity at rest and who may have signs of right ventricular failure. Dyspnea and/or fatigue may be present at rest, and symptoms are increased by almost any physical activity.

catheterization.[19] Echocardiography can also be used to assess treatment interventions and to follow disease progression.[17] Because PAH commonly occurs in the setting of connective tissue disease, serologic markers for these diseases (e.g., scleroderma, systemic lupus erythematosus, rheumatoid arthritis, myositis) should be obtained to confirm or exclude these diagnoses.[17] HIV is associated with an increased prevalence of PAH, and HIV testing should be done in the PAH workup.[1,17,19] Chronic thromboembolic pulmonary hypertension should be evaluated with ventilation–perfusion lung scans and/or pulmonary angiography. Pulmonary function testing and arterial blood oxygenation should be evaluated, and the diffusing capacity of carbon monoxide may be particularly helpful in systemic sclerosis and PAH.[17] Right-heart catheterization is the diagnostic "gold standard." It establishes the diagnosis of PAH, evaluates pulmonary vasoreactivity, and guides therapy.[17] In patients with PAH, serial determinations of functional class, exercise capacity (assessed by the 6-minute walk distance), and serial biomarkers provide benchmarks for disease severity, response to therapy, and progression.[19]

6 Right-heart catheterization provides important prognostic information and can be used to assess pulmonary vasoreactivity with the administration of fast-acting, short-duration vasodilators to determine the extent of vascular smooth muscle constriction and vasodilator response to calcium channel blockers (strength of recommendation: A for IPAH; E/C for associated pulmonary arterial hypertension [APAH]).[12] Table 35–3 lists the grading criteria for recommendations. Table 35–4 lists commonly used agents and their dosages. The consensus definition of a positive response is defined as reduction of mPAP by at least 10 mm Hg to a value of 40 mm Hg or less. Patients with this response are most likely to have a beneficial hemodynamic and clinical response to treatment with calcium channel blockers.[1,17] Those failing to achieve this response should not be treated with calcium channel blocker therapy. Those achieving this acute response may be treated with calcium channel blockers but need to be followed closely for safety and efficacy. Patients most likely to respond to calcium channel blockers are those with IPAH.[17] Based on a study conducted by Sitbon et al. only approximately 13% will display acute vasoreactivity.[28] About half of these patients lose this response when tested 1 year later. A significant vasodilator response may reflect an earlier stage of disease or a qualitatively different disease process.[12]

TABLE 35-4 Agent for Vasodilator Testing in Pulmonary Arterial Hypertension

	Epoprostenol	**Adenosine**	**NO**
Route	IV	IV	Inhaled
Dose range	2–10 ng/kg/min	50–250 mcg/kg/min	10–80 ppm
Dosing increments	2 ng/kg/min every 15 minutes	50 mcg/kg/min every 2 minutes	10–80 ppm for 5 minutes
Common side effects	Headache, flushing, nausea	Chest tightness, dyspnea	None

NO, nitric oxide; IV, intravenous; ppm, parts per million.

CLINICAL PRESENTATION OF PULMONARY ARTERIAL HYPERTENSION

Symptoms

- Exertional dyspnea, fatigue, weakness, complaints of general exertion intolerance, dyspnea at rest as the disease progresses, exertional chest pain, syncope, lower extremity edema
- Symptoms of Related Conditions: Orthopnea, paroxysmal nocturnal dyspnea as a result of left-sided heart disease; Raynaud phenomenon, arthralgia, or swollen hands and other symptoms of connective tissue disease; a history of snoring as reported by the patient's partner may be a consequence of sleep-disordered breathing and can be associated with PAH.

Symptoms of Disease Progression

- Leg swelling, abdominal bloating and distension, anorexia, and more profound fatigue may develop as right ventricular dysfunction and tricuspid valve regurgitation evolve.

Signs

- Accentuated component of S_2 audible at the apex of the heart, early systolic ejection click, midsystolic ejection murmur, palpable left parasternal lift, right ventricular S_4 gallop, and a prominent "a" wave.

Signs of Advanced Disease

- Diastolic murmur of pulmonary regurgitation and holosystolic murmur of tricuspid regurgitation, hepatojugular reflux, a pulsatile liver, right ventricular S_3 gallop, marked distension of jugular veins, peripheral edema, low blood pressure, diminished pulse pressure, cool extremities suggesting markedly reduced cardiac output and peripheral vasoconstriction; cyanosis (suggests right-to-left shunting), digital clubbing, rales, dullness, decreased breath sounds, accessory muscle use, wheezing, prolonged exhalation; peripheral venous insufficiency (suggests venous thrombosis or pulmonary thrombotic disease).

Diagnostic Tests

- Electrocardiogram for chamber enlargement, chest radiography to detect enlarged pulmonary arteries, Doppler echocardiography to calculate right ventricular/right atrial pressure and pulmonary diastolic pressure, pulmonary function testing and arterial blood oxygenation; ventilation-perfusion scanning, computed tomography, or magnetic resonance imaging can be used to exclude other diagnoses; right-heart catheterization may be used to confirm the presence of PAH and to guide therapy.
- Tests for connective disease or other risk factors.

TREATMENT

Pulmonary Arterial Hypertension

DESIRED OUTCOMES

7 The goals of treatment are alleviation of symptoms, improvement in the quality of life, prevention of disease progression, and improvement in survival.[13,29] While the first two outcomes are clearly obtainable based on data from randomized trials, controversy exists over improvement in survival with current treatment regimens. In a meta-analysis performed by Macchia et al. of 16 trials involving 1,962 patients, no change in total mortality was seen.[30] Up to 80% of the patients were in functional classes III/IV, with a median walking distance of 330 meters at baseline. Overall, experimental treatments were associated with a nonsignificant reduction in all-cause mortality, a minor but statistically significant improvement in exercise capacity, and an improved dyspnea status by at least one functional class. Changes in exercise capacity were not found to be predictive of a survival benefit.[30] Because most of the patients had advanced disease, the potential for a reduction in mortality may have been minimized, and less severely ill patients may have better outcomes.

However, a recent meta-analysis by Galie et al. of 21 trials including 3,140 patients found different results. In contrast to the previous meta-analysis, this study included six new randomized, controlled trials not previously evaluated and excluded one trial performed in lung fibrosis patients. Investigators found that active treatment of PAH resulted in a 43% reduction in mortality. Patients experienced an improvement in exercise capacity, determined by change in 6-minute walk distance. Approximately half of the patients were functional class III at baseline. With active treatment, functional class improved and number of hospitalizations was reduced. This meta-analysis offers support that treatment does improve survival; unfortunately, overall mortality remains high.[31] In addition, individual trials also show survival benefit, at least in the short term (i.e., 3 years).[32]

GENERAL APPROACH TO TREATMENT

Treatment of PAH may be categorized into nonpharmacologic, surgical, and pharmacologic interventions. 8 The principal endothelial abnormalities that are current pharmacologic therapeutic targets include (a) supplementing endogenous vasodilators, (b) inhibiting endogenous vasoconstrictors, and (c) reducing endothelial platelet interaction and limiting thrombosis. Nonpharmacologic therapy can be quite broad and should be used when clinically appropriate. Surgical therapy is indicated in certain situations and includes atrial septostomy, pulmonary thromboendarterectomy for chronic thromboembolic pulmonary hypertension, and lung or heart–lung transplantation (for disease that is not responsive to medical therapy).[29]

NONPHARMACOLOGIC THERAPY

9 Nonpharmacologic therapy is frequently used to address comorbid conditions that often accompany PAH. In patients with obstructive sleep apnea and PAH, positive airway pressure therapy should be provided.[6] Pulmonary thromboendarterectomy for PAH caused by chronic, recurrent thromboembolic disease improves hemodynamics, functional status, and survival. Pregnancy should be avoided; all females of child-bearing age should be counseled on the risks of pregnancy due to high mortality rates.[6] Immunization against influenza and pneumococcal disease should be provided according to standards for patients with serious cardiopulmonary disease.[13] Hypoxemia may aggravate vasoconstriction in patients with PAH, and it is advisable to avoid hypobaric hypoxia starting with altitudes between 1,500 and 2,000 meters. Commercial airplanes are pressurized to equivalent altitude between 1,600 and 2,500 meters and supplemental oxygen in PAH patients should be considered.[18] Patients should adhere to a diet of 2,400 milligrams of sodium or less per day to avoid fluid retention (predisposing to right-heart failure).[13,19] Cardiopulmonary rehabilitation improves functional status and is safe and important for patients with PAH.[33] Patients with PAH are sensitive to anemia. Complete blood count should be monitored and anemia treated as appropriate.[18] Patients with long-standing hypoxia, such as those with right-to-left shunts, develop erythrocytosis. Phlebotomies may be indicated in symptomatic patients to prevent complications of hyperviscosity. PAH patients are affected by a variable degree of anxiety and/or depression that can have a profound impact on their quality of life. Support groups and psychological counseling can be helpful to improve understanding and acceptance of the disease.[18]

Patients with PAH are frequently anticoagulated with warfarin; therefore, patients should avoid drugs that interact with warfarin or those that potentially increase the risk of gastrointestinal hemorrhage (e.g., nonsteroidal anti-inflammatory drugs such as ibuprofen and aspirin), as anticoagulation in PAH is frequently considered. Nonsteroidal antiinflammatory drugs may also worsen renal function and are of particular concern in patients with low cardiac output or azotemia. Angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, and β-blockers may cause hypotension and right-heart failure and should be used with caution in PAH.

PHARMACOLOGIC THERAPY

The number of potential therapies for PAH has expanded dramatically in the past decade. Multiple drugs have been developed specifically for treatment of PAH in addition to adjunctive therapy with anticoagulation and oxygen, as well as other therapies to treat comorbidities. Figure 35–2 illustrates the current recommended treatment algorithm based on the most recent guidelines.[6,29]

Conventional Pharmacologic Treatment

10 Conventional therapy includes oral anticoagulants, diuretics, oxygen, and digoxin.[1,19] The rationale for oral anticoagulants in patients with PAH is based on the presence of traditional risk factors for venous thromboembolism, such as heart failure and sedentary lifestyle, as well as on the demonstration of thrombotic predisposition and thrombotic changes in the pulmonary microcirculation. The target international normalized ratio in most centers is 1.5 to 2.5.[1,17] In recent trials, 50% to 85% of patients have been anticoagulated; the highest prevalence has been in IPAH patients in New York Heart Association classes III and IV.[15] Anticoagulation is recommended for patients with IPAH (strength of recommendation: E/B).[13,19,29]

Diuretics are used in patients with decompensated right-heart failure and with associated findings of increased central venous pressure, abdominal organ congestion, peripheral edema, and ascites.[13] Appropriate diuretic therapy in right-heart failure allows clear symptomatic and clinical benefits in patients with PAH (strength of recommendation: E/A). Diuretics need to be used carefully as these patients should be maintained at as close to a euvolemic state as possible. There are no randomized trials of diuretic therapy in PAH. Approximately 50% to 70% of patients with PAH receive diuretic therapy.

Although oxygen saturation should be maintained at approximately 90%, there are no data currently available regarding the effects of long-term oxygen treatment in PAH (strength of recommendation: E/A). Oxygen treatment in patients with PAH associated with shunts (Eisenmenger syndrome) is controversial.[13]

Digoxin use in PAH is based on judgment rather than scientific evidence of efficacy. Digoxin can be used for PAH patients with right-heart failure as adjunctive therapy along with diuretics to control symptoms. Digoxin may be useful in PAH patients who develop atrial flutter to slow ventricular rate.[13,17] Current guidelines give digoxin a recommendation of E/C.[29] There are no long-term trials,

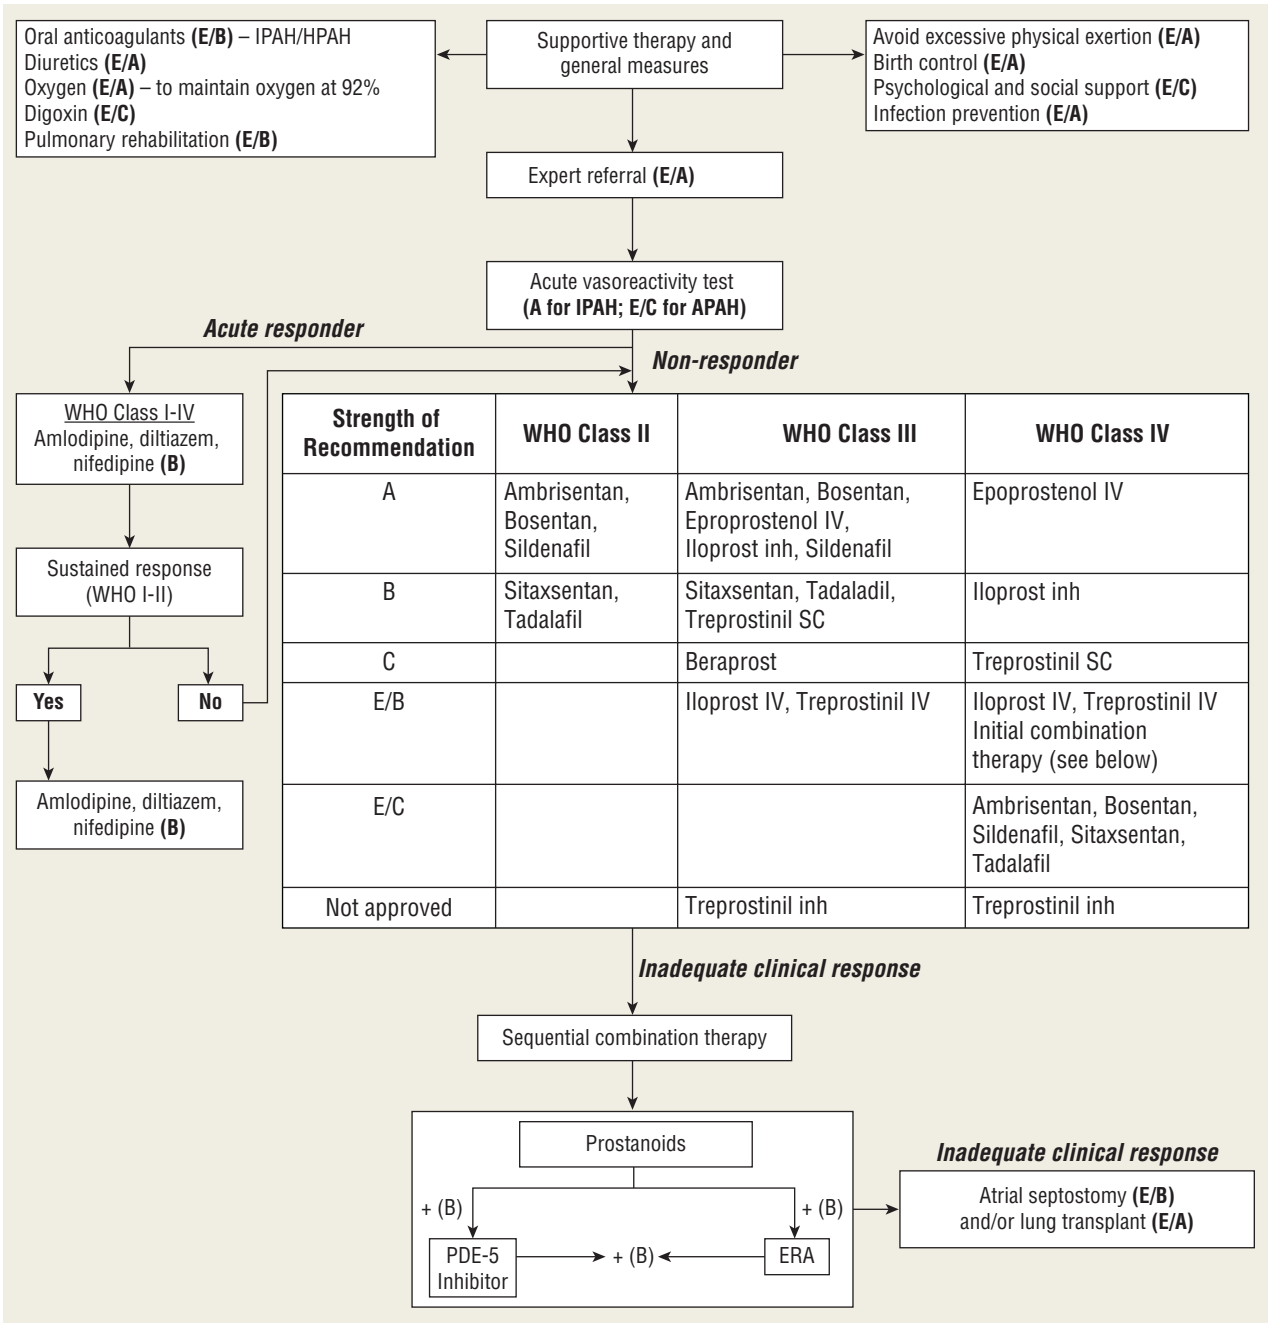

FIGURE 35-2. Treatment algorithm for pulmonary arterial hypertension (PAH). Designators (A), (B), (C), (D), (E/A), (E/B), and (E/C) are defined in Table 35–3. (CCB, calcium channel blocker; FC, functional class; IPAH, idiopathic pulmonary arterial hypertension; APAH, associated pulmonary arterial hypertension; HPAH, heritable pulmonary arterial hypertension.) *(Barst RJ, Gibbs SR, Ghofrani HA, et al. Updated evidence-based treatment algorithm in pulmonary arterial hypertension. JACC 2009;54(suppl S):S78–S84.)*

and benefit is uncertain. Optimal plasma concentrations for digoxin in PAH are unknown; however, in light of recent trials of digoxin in left systolic dysfunction, plasma concentrations should probably be in the range of 0.5 to 0.8 ng/mL. Patients on digoxin should receive periodic monitoring of potassium.

Specific Pharmacologic Therapy

In recent years, there has been a surge in availability of drug therapy for the treatment of PAH. Figure 35–3 illustrates the timeline of drug approval over the last few decades.

Synthetic Prostacyclin and Prostacyclin Analogs

Prostacyclin is produced predominantly by endothelial cells, and it induces potent vasodilation of all vascular beds. It is also a potent inhibitor of platelet aggregation and possesses cytoprotective and antiproliferative activities. Prostacyclin synthase expression is reduced in pulmonary arteries, and urinary excretion of prostacyclin metabolites is reduced in PAH. Epoprostenol (Flolan) is a synthetic analog of prostacyclin and has a short half-life of 3 to 5 minutes; consequently, it must be given by continuous intravenous infusion. In controlled trials lasting up to 3 months, epoprostenol improved 6-minute walk distance, hemodynamics, and clinical events.[34–36] Long-term epoprostenol is initiated at a dose ranging from 2 to 4 ng/kg/min and increased at a rate limited by side effects (flushing, headache, diarrhea, jaw pain, backache, abdominal cramping, foot/leg pain, and, rarely, hypotension). Because the drug must be given by a pump to provide a continuous infusion, infection, catheter obstruction, and sepsis are potential complications. A Centers for Disease

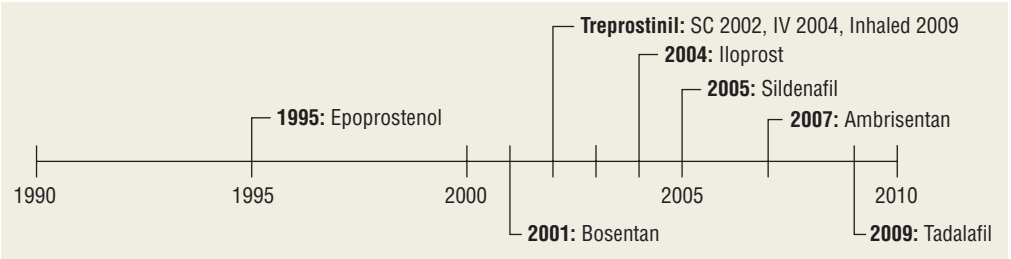

FIGURE 35-3. Timeline of pulmonary arterial hypertension (PAH) medication approvals. Epoprostenol: 1995; Treprostinil: SC 2002, IV 2004, Inhaled 2009, PO not approved; Iloprost: 2004; Bosentan: 2001; Ambrisentan: 2007; Sildenafil: 2005; Tadalafil: 2009.

Control and Prevention study found that bloodstream infections occurred with epoprostenol and treprostinil in the range of 0.3 to 2.1 per 1,000 medicine days (approximately one infection every 3 years) when these drugs are given by the intravenous route. The target dose for the first 2 to 4 weeks is around 10 to 15 ng/kg/min, and periodic dose increases are then required to maximize efficacy and to avoid tolerance. Optimal doses are variable but are in the range of 25 to 40 ng/kg/min.[13,18] Observational series have documented an improvement in survival in patients with IPAH compared with either historical control or predicted survival based on the National Institutes of Health Registry equation.[36,37] Based on current guidelines, epoprostenol is indicated for World Health Organization (WHO) functional class III and IV (strength of recommendation: A).[29]

Treprostinil (Remodulin) is a stable analog of prostacyclin given for subcutaneous (SC) or intravenous (IV) infusion approved for functional classes II, III, and IV.[13] The major advantages of treprostinil over epoprostenol include ease of use and increased safety due to a longer half-life, lowering the risk of rebound effects that may happen with drug interruption.[1] Treprostinil has been shown to improve 6-minute walk distance and hemodynamics with outcomes that are similar to epoprostenol. [38,39] In clinical trials, the greatest exercise improvement was observed in patients who were more compromised at baseline and in patients who could tolerate doses in the upper quartile (>13.8 ng/kg/min). The initial dose for treprostinil is 1.25 ng/kg/min by either the SC or the IV route. If not tolerated, the dose should be reduced to 0.625 ng/kg/min and retitration attempted at 4 weeks. If transitioning from epoprostenol to treprostinil, start with 10% of the epoprostenol dose. Dose may be increased by 1.25 ng/kg/min but no more than 2.5 ng/kg/min per week. Infusion site pain is the most common side effect of treprostinil, leading to discontinuation of the treatment in 8% of patients and limiting dose increase in other patients.[18] Other side effects are similar to epoprostenol. Based on international guidelines, treprostinil is recommended for functional class III (SC administration, strength of recommendation: B; IV administration, strength of recommendation: E/B), and functional class IV (SC administration, strength of recommendation: C; IV administration, strength of recommendation: E/B).[29]

Inhaled treprostinil (Tyvaso) was approved by the FDA in July 2009 to improve exercise capacity in functional class III patients. In a randomized, double-blind, 12-week trial, patients receiving inhaled treprostinil experienced a 20-meter improvement in 6-minute walk distance compared with those on placebo (p <0.0006). All patients included in the trial were concurrently receiving bosentan or sildenafil for at least 3 months.[40] An open-label extension of the trial found that inhaled treprostinil provided sustained benefit and was safe and efficacious over a 2-year period.[41] The approved dosing of inhaled treprostinil is 3 breaths (18 mcg each) four times daily during waking hours. The dose may be titrated based on patient tolerance at 1- to 2-week intervals to maximum dose of 9 breaths four times daily. While inhaled treprostinil avoids the infusion-related complications of the other prostacyclin analogs, use is cautioned in patients with acute pulmonary infections or underlying lung disease. The most common adverse effects seen in clinical trials include throat irritation, cough, headache, nausea, dizziness, and flushing. Inhaled treprostinil may also cause systemic hypotension, and patients should be monitored carefully if they are concurrently on diuretics, antihypertensives, or other vasodilators. Further studies are being performed to evaluate the risk of oropharyngeal and pulmonary toxicities in patients on inhaled treprostinil. Current guidelines have not yet assigned a strength of recommendation for inhaled treprostinil use.[29] Iloprost (Ilomedin, Ventavis) is a prostacyclin analog that is given by inhalation using a dosing system provided by the manufacturer (ADD system) with the initial inhaled dose being 2.5 mcg 6 to 9 times/day up to every 2 hours during waking hours. The dose should be titrated and maintained at 5 mcg/dose if tolerated. In a 3-month, randomized, double-blind, placebo-controlled trial, iloprost via inhalation provided at least a 10% improvement in 6-minute walking distance and improvement in functional class.[42] Iloprost may also be used as add-on therapy to bosentan.[43] Adverse effects are similar to other prostacyclin analogs with the exception of infectious complications related to catheter use for drug delivery. Inhaled iloprost is indicated for functional class III (strength of recommendation: A) and functional class IV (strength of recommendation: B).[29]

Endothelin Receptor Antagonists ⑫ Endothelin-1 (ET-1), a peptide produced primarily by the vascular endothelial cells, is characterized as a powerful vasoconstrictor and mitogen for smooth muscle. Activation of the ET-1 system has been shown in both plasma and lung tissue of PAH patients. Bosentan (Tracleer) is an orally active dual ET_A and ET_B receptor antagonist that improves exercise capacity, functional class, hemodynamics, echocardiographic and Doppler variables, and time to clinical worsening.[44,45] In one of the larger studies with bosentan, patients were started on 62.5 mg twice daily for 4 weeks followed by 125 mg or 250 mg twice daily for a minimum of 12 weeks.[44] Both doses were better than placebo, and the higher dose provided greater improvement in 6-minute walking distance. Increases in hepatic aminotransferases occurred in 11% of patients and were dose dependent. The mechanism of increased liver enzymes is thought to be competition by bosentan and its metabolites with the biliary excretion of bile salts, resulting in retention of bile salts that can be cytotoxic to hepatocytes.[46] Bosentan should be started at 62.5 mg twice daily in adults and adolescents for 4 weeks. After 4 weeks of therapy, the dose should be increased to 125 mg twice daily. If liver function tests are confirmed to be in the range of three to five times the upper limit of normal, reduce the daily dose or interrupt treatment. If liver function tests return to pretreatment levels, bosentan may be continued or reintroduced if indicated. Liver function tests should be monitored at baseline and monthly thereafter, and monthly pregnancy testing is required in females (category X). Complete blood count should be monitored every 3 months as bosentan has been associated with anemia. Bosentan is indicated for WHO functional class II and III (strength of

recommendation: A) as well as functional class IV (strength of recommendation: E/C).[29]

Ambrisentan (Letairis) is a once-daily selective ET_A receptor antagonist that improves exercise capacity and hemodynamics and delays clinical worsening in PAH.[47,48] Two large (n = 202 and 192) trials recently evaluated the efficacy of ambrisentan compared with placebo (Ambrisentan in Pulmonary Arterial Hypertension, Randomized, Double-Blind, Placebo-Controlled, Multicenter, Efficacy Study 1 and 2; or ARIES 1 and 2). In 12 weeks, both studies demonstrated a significant improvement in functional capacity at doses of 2.5 mg, 5 mg, and 10 mg daily (range of 31–59 m). However, greater response was seen with increased doses. All doses were well tolerated, with no patients on therapy experiencing an increase in liver function tests (LFTs) >3 times the upper limit of normal. Similar to bosentan, ambrisentan has liver toxicity and is category X for pregnancy. Liver toxicity is less with ambrisentan (0.8% in 12-week trials and 2.8% for up to 1 year), but monthly monitoring is still required.[13] Common side effects include peripheral edema, nasal congestion, flushing, and palpitations. Treatment should be initiated with 5 mg once daily and increased to 10 mg once daily if required. Ambrisentan is recommended for WHO functional class II and III (strength of recommendation: A) and may be used for WHO functional class IV (strength of recommendation: E/C).[29]

Sitaxsentan (Thelin) is a highly selective, orally active ET_A receptor antagonist shown to improve exercise capacity, hemodynamics, and clinical events in PAH at doses of 100 to 300 mg daily.[49–52] In clinical trials evaluating sitaxsentan 100 mg daily versus placebo, sitaxsentan therapy resulted in improvement in 6-minute walk distance and functional class.[53] Sitaxsentan may increase the international normalized ratio because of inhibition of cytochrome P450 2C9 if patients are also taking warfarin. Sitaxsentan may be associated with lower rates of hepatotoxicity than other endothelin antagonists.[52] Based on the 4th World Health Symposium, sitaxsentan is recommended for WHO functional class II and III (strength of recommendation: B) as well as class IV (strength of recommendation: E/C).[29] To date, sitaxsentan is not FDA approved in the United States.

Phosphodiesterase Inhibitors 13 Sildenafil (Revatio) is a potent and highly specific phosphodiesterase-5 inhibitor that is approved for erectile dysfunction but also has been shown to reduce mPAP and improve functional class. Sildenafil exerts its pharmacologic effect by increasing the intracellular concentration of cyclic guanosine monophosphate, leading to vasorelaxation and antiproliferative effects on vascular smooth muscle cells. In a recent trial, sildenafil induced a significant reduction in mPAP and vascular resistance, and functional capacity improved (an average of +37 m). Sildenafil improved endothelial dependent vasodilation, and reduced plasma concentrations of endothelin-1 (from 4.5 ± 0.6 to 3.1 ± 0.7 pg/mL; p <0.0001) and von Willebrand factor (from 183.1 ± 10.1 to 149.1 ± 17.6 mU/mL; p <0.0001).[54] In a year-long study, sildenafil in chronic thromboembolic pulmonary hypertension improved 6-minute walking distance and hemodynamics.[55] Other studies have found similar beneficial results.[56–58] The FDA-approved dose is 20 mg by mouth three times per day; however, much higher doses are routinely used clinically. Common adverse effects include headaches, flushing, epistaxis, dyspepsia, and diarrhea. Changes in vision have been reported, including blue-tinted vision and sudden loss of vision. In the event of sudden loss of vision, the drug should be stopped. Concurrent nitrate therapy may lead to excessive blood pressure reduction, and this combination should be avoided. Based on the current guidelines, sildenafil is recommended for functional class II and III patients with PAH (strength of recommendation: A) in addition to functional class IV patients (strength of recommendation: E/C).[29]

Another phosphodiesterase-5 inhibitor, tadalafil (Adcirca), was approved by the FDA in May 2009 for the treatment of PAH. In a 16-week study, tadalafil 40 mg daily significantly improved exercise capacity (an average of +33 m; p <0.01) and quality of life measures. Tadalafil 40 mg also improved the time to clinical worsening (p = 0.041), which has not been demonstrated with sildenafil. Fifty-three percent of patients in this study were also on background bosentan therapy. Treatment-naïve patients demonstrated not only greater improvement in exercise capacity than those on bosentan therapy (+44 m vs. 23 m) but also greater improvement on all secondary outcomes. One possible explanation is decreased tadalafil levels as bosentan is a potent CYP450 3A4 inducer. Higher doses of tadalafil may be required in patients on concurrent bosentan therapy.[59] The most commonly reported adverse events were headache, myalgia, and flushing. The recommended dose is 40 mg by mouth once a day.[59] Concurrent use with nitrate therapy should also be avoided with tadalafil. Current guidelines indicate tadalafil for functional class II and III (strength of recommendation: B) and functional class IV (strength of recommendation: E/C).[29]

Calcium Channel Blockers 14 A very small number of patients with IPAH demonstrating a favorable response to acute vasodilator testing will do well with calcium channel blockers (CCBs). As described previously, IPAH patients are most likely to respond to acute vasodilators and CCBs, but the number responding on long-term treatment is small (approximately 7%).[28] Large reductions in MPAP predict a better response to long-term CCBs. The preferred drugs are dihydropyridine CCBs as they lack the negative inotropic effects seen with verapamil. Diltiazem may be used in patients with tachycardia to slow heart rate through atrioventricular node blockade. If left ventricular systolic dysfunction is present, diltiazem and verapamil should not be used. Assessment of CCB therapy should occur soon after initiation, and if improvement in functional class to class I or II is not seen, additional or alternative PAH therapy should be instituted. CCBs should not be used empirically to treat PAH in the absence of demonstrated acute vasoreactivity.[29] In acute responders, calcium channel blockers may be used in WHO functional classes I through IV (strength of recommendation: B).[29] The doses of these drugs are relatively high—that is, up to 120 to 240 mg/day for nifedipine and 240 to 720 mg/day for diltiazem—however, initial doses should be much lower and titrated upward to response.[18]

Combination Therapy 15 Combination therapy is an attractive option to address the multiple pathophysiologic mechanisms in PAH, resulting in improvement in hemodynamics, symptoms, and exercise capacity. Combination therapy can be pursued by the simultaneous initiation of two (or more) treatments or by the addition of a second (or third) agent if previous treatment has been insufficient. Potential indications for combination therapy include signs of right-heart failure, 6-minute walk distance <380 m, and persistent functional class III or IV symptoms despite active treatment.[17] Hoeper found that following a goal-oriented treatment approach using combinations of bosentan, sildenafil, and inhaled iloprost significantly improved the combined end point of death, lung transplantation, and need for intravenous iloprost treatment.[60]

Bosentan, when combined with epoprostenol, improved hemodynamics, exercise capacity, and functional class, though this result was nonsignificant.[61] In patients with PAH who are deteriorating despite chronic treatment with prostanoids, the addition of bosentan or sildenafil results in improvement in pulmonary hemodynamics and exercise based on uncontrolled studies.[62,63] Addition of sildenafil to long-term epoprostenol therapy resulted in significant improvements in 6-minute walk distance, mPAP, cardiac output, and time to clinical worsening.[64] Two studies have evaluated the combination of inhaled iloprost with existing bosentan therapy, and one found a nonsignificant improvement in 6-minute walk distance. One study was terminated early due to a futility analysis of the predetermined sample size.[62] Addition of tadalafil to background bosentan therapy resulted in improvement in 6-minute

walk distance.[59] Inhaled treprostinil in combination with bosentan or sildenafil also increased 6-minute walk distance.[40] An increase in adverse effects may be experienced with combination therapy.[64]

Sequential combination therapy is recommended for patients with inadequate clinical response to monotherapy; combinations of prostanoids, phosphodiesterase-5 inhibitors, and endothelin antagonists may be used (strength of recommendation: B).[29] Initial combination therapy may be necessary in WHO functional class IV patients (strength of recommendation: E/C).[29] More specific information concerning individual drugs used for PAH are shown in Table 35–5, and a summary of evidence for combination therapy is shown in Table 35–6.

TABLE 35-5 Drug Class Information

Drug	Mechanism of Action	Pharmacokinetics	Adverse Events	Drug–Drug Interactions	Dosing
Synthetic prostacyclin and prostacyclin analogs					
Epoprostenol (Flolan)	Potent vasodilator of all vascular beds	Metabolized to 2 major and 14 minor metabolites Half-life 3–5 minutes Stable for 8 hours at room temperature	Flushing, jaw pain, diarrhea, headache, backache, foot and leg pain, abdominal cramping, nausea, hypotension (rarely)	May increase risk of bleeding with anticoagulants Sympathomimetics antagonize vasodilatory effects Additive hypotensive effects with monoamine oxidase inhibitors	Starting dose 2–4 ng/kg/ min IV, titrate up to 20–40 ng/kg/min
IV/SC treprostinil (Remodulin)	Direct vasodilator of systemic and pulmonary vascular beds and inhibits platelet aggregation	Metabolized hepatically via CYP2C8 enzymes Half-life 4 hours	Cardiovascular dilation, diarrhea, nausea, headache, jaw pain, injection site pain, rash, and pruritus	May increase risk of bleeding with anticoagulants Sympathomimetics antagonize vasodilatory effects Additive hypotensive effects with monoamine oxidase inhibitors	Initially 1.25 ng/kg/min continuous SC or IV infusion Decrease to 0.625 ng/kg/min if not tolerated Increase by no more than 1.25 ng/kg/min weekly for the first 4 weeks of therapy and no more than 2.5 ng/kg/min weekly for the duration of therapy
Inhaled treprostinil (Tyvaso)	Direct vasodilator of systemic and pulmonary vascular beds and inhibits platelet aggregation	Metabolized hepatically via CYP450 2C8 enzymes Half-life 4 hours	Throat irritation, cough, hemoptysis, pneumonia, syncope, flushing, nausea, headache	May increase risk of bleeding with anticoagulants Sympathomimetics antagonize vasodilatory effects Additive hypotensive effects with monoamine oxidase inhibitors	Initially 3 breaths (18 mcg) via oral inhalation four times daily during waking hours (approximately 4 hours apart) Reduce to 1–2 breaths if 3 breaths not tolerated; increase to 3 breaths when tolerance improves Goal maintenance dose is 9 breaths (54 mcg) per treatment four times daily; titrate by increasing 3 breaths at 1- to 2-week intervals as tolerated
Iloprost (Ventavis)	Dilates systemic and pulmonary arterial vascular beds, alters pulmonary vascular resistance and suppresses vascular muscle proliferation Potent endogenous inhibitor of platelet aggregation	Metabolized hepatically via beta oxidation of the carboxyl side chain Half-life 20–30 minutes	Flushing, hypotension, headache, nausea, trismus, cough, flulike syndrome, jaw pain	Increased hypotensive effects when used with vasodilators and antihypertensive medications Anticoagulants and antiplatelet medications may increase the risk of bleeding	Initially 2.5 mcg inhaled six to nine times daily (dosing at ≥2 hour intervals while awake) May titrate to 5 mcg per dose with a maximum daily dose of 45 mcg
Endothelin receptor antagonists					
Bosentan (Tracleer)	Competitive antagonist for type A and B endothelin receptors, which mediate vasoconstriction and vasodilation Lowers systemic vascular resistance, pulmonary vascular resistance, and mean pulmonary arterial pressure	Bioavailability 50% >98% protein bound Metabolized by CYP2C9 and 3A4; also inducer of CYP 2C9, 3A4, and 2C19 Half-life 5 hours	Headache, flushing, abnormal hepatic enzymes, edema, reduced hemoglobin concentrations Black box warning to monitor serum aminotransferases at baseline and monthly during therapy	Known substrates of CYP3A4 (e.g., cyclosporine A, glyburide, hormonal contraceptives) Known substrates of CYP2C9 (e.g., warfarin)	Initially 62.5 mg orally twice daily for 4 weeks Then increase to 125 mg orally twice daily Available through Tracleer Access Program

(continued)

TABLE 35-5 Drug Class Information (continued)

Drug	Mechanism of Action	Pharmacokinetics	Adverse Events	Drug–Drug Interactions	Dosing
Ambrisentan (Letairis)	Selective antagonist for type A endothelin receptors, which mediates vasoconstriction and vasodilation Lowers systemic vascular resistance, pulmonary vascular resistance, and mean pulmonary arterial pressure	Bioavailability unknown 99% protein bound Metabolized by CYP3A4, 2C19, and uridine glucuronyltransferases, substrate of organic anion transport protein and P-glycoprotein Half-life-9 hours	Peripheral edema, flushing, palpitations, elevated hepatic enzymes, headache, nasal congestion	Cyclosporine will increase ambrisentan levels Known inhibitors of CYP3A4 (e.g., amiodarone, erythromycin) Known inhibitors of CYP2C19 (e.g., cimetidine, clopidogrel, efavirenz) Known inducers of CYP3A4 (e.g., carbamazepine, rifampin)	Initial dose 5 mg orally daily, titrated to maximum dose of 10 mg daily Available through Letairis Education and Access Program
Sitaxsentan (Thelin)	Selective antagonist for type A endothelin receptors, which mediates vasoconstriction and vasodilation Lowers systemic vascular resistance, pulmonary vascular resistance, and mean pulmonary arterial pressure	Bioavailability >90% >99% protein bound Moderate inhibitor of 2C9, 2C19, 3A4 Half-life 6.5 hours	Peripheral edema, nausea, decreased hemoglobin, fulminant hepatitis, increased aminotransferases, headache, dizziness, nasal congestion	Cyclosporine will increase sitaxsentan levels 2C9 inhibitor (will increase known 2C9 substrates, e.g., phenytoin, tolbutamide, warfarin) Increase risk of bleeding with warfarin	100–300 mg orally daily Not yet available in United States
Phosphodiesterase inhibitors					
Sildenafil (Revatio)	Increases the intracellular concentration of cyclic guanosine monophosphate (cGMP) resulting in vasorelaxation and antiproliferative effects on smooth muscle cells	Bioavailability 40% 96% protein bound Metabolized by CYP450 3A4 (major) and 2C9 (minor) Half-life 4 hours	Headache, flushing, dyspepsia, nasal congestion, dizziness, and rash	Known inhibitors of CYP3A4 and 2C9 (e.g., bosentan, cimetidine, fluvoxamine) Known inducers of CYP3A4 (e.g., rifampin, carbamazepine) Concurrent use with nitrates potentiates hypotensive effects	20 mg orally three times daily, taken at least 4–6 hours apart; 50 mg twice daily may be appropriate for more severe cases No greater efficacy with higher doses
Tadalafil (Adcirca)	Increases the intracellular concentration of cyclic guanosine monophosphate (cGMP) resulting in vasorelaxation and antiproliferative effects on smooth muscle cells	Bioavailability unavailable 94% protein bound Metabolized by CYP4503A4 (major) Half-life 15 hours	Headache, flushing, dyspepsia, myalgia, nausea, nasal congestion, nasopharyngitis, pain in extremity	Known inhibitors of CYP3A4 (e.g., bosentan, amiodarone) Known inducers of CYP3A4 (e.g., rifampin, carbamazepine) Concurrent use with nitrates potentiates hypotensive effects	40 mg orally once daily, with or without food Not recommended to divide the dose
Calcium channel blockers					
Nifedipine extended release (Procardia XL, Nifedical XL, Adalat CC)	Blocks the influx of extracellular calcium, causing vasodilation; more potent vasodilator than diltiazem	Bioavailability 90% Extensive first-pass effect reduces bioavailability to 86% Metabolized by CYP3A4 Half-life 2–5 hours	Peripheral edema, headache, dizziness, constipation, flushing	Known inhibitors of CYP3A4 (e.g., amiodarone, erythromycin) Known 3A4 inducers (e.g., rifampin, carbamazepine)	Start at reduced dose of 30 mg orally twice daily and titrate to 120–240 mg daily
Diltiazem (Cardia XT, Cardizem CD, LA, SR, Taztia XT)	Blocks the influx of extracellular calcium, causing vasodilation	Bioavailability 80% Extensive first pass effect reduces bioavailability to 40% to 60% Metabolized by CYP3A4 Half-life 4–6 hours	Gastrointestinal effects, negative inotropic effects, headache, flushing, peripheral edema	Known inducers of CYP3A4 (e.g., rifampin, carbamazepine) Known inhibitors of CYP3A4 (e.g., amiodarone, erythromycin)	Start at reduced dose of 60 mg orally three times daily and titrate to 240–720 mg daily
Amlodipine (Norvasc)	Blocks the influx of extracellular calcium, causing vasodilation; more potent vasodilator than diltiazem	Bioavailability 52% to 88% 93% protein bound Metabolized by CYP3A4 Half-life 35 hours	Palpitations, peripheral edema, fatigue, dizziness, headache, flushing	Known inducers of CYP3A4 (e.g., rifampin, carbamazepine) Known inhibitors of CYP3A4 (e.g., amiodarone, erythromycin)	Start at reduced dose of 2.5 mg orally daily, titrated to maximum dose of 40 mg daily

TABLE 35-6 Summary of Evidence on Combination Therapy

Drug Combination	Main Outcomes: Improvement in 6-Minute Walk Distance	Other Evaluations
Bosentan ± inhaled iloprost		
STEP trial ($n = 67$)	26 m ($p = 0.051$)	Improvement in functional class, time to clinical worsening, and postinhalation hemodynamics ($p < 0.05$)
COMBI trial ($n = 40$)	Terminated early due to futility analysis	
Epoprostenol ± oral therapy		
BREATHE-2 ($n = 33$) (Epoprostenol ± bosentan)	No difference	Trend toward improvement in hemodynamics, exercise capacity, and functional class at 16 weeks
PACES trial ($n = 267$) (Epoprostenol ± sildenafil)	28.8 m ($p < 0.001$)	Improvement in mean pulmonary arterial pressure, cardiac output, time to clinical worsening, and health-related quality of life; no change in Borg dyspnea score
Oral therapy combination		
PHIRST trial ($n = 405$; $n = 171$ on background bosentan) (Tadalafil ± bosentan)	23 m	Improvement in time to clinical worsening, incidence of clinical worsening, and health-related quality of life
Oral Therapy ± Inhaled Treprostinil		
TRIUMPH I trial ($n = 235$)	20 m ($p < 0.0006$)	No improvement in time to clinical worsening, change in functional class, or Borg dyspnea score

BREATHE-2, Bosentan Randomized Trial of Endothelin Antagonist Therapy; COMBI, Combination Therapy of Bosentan and Aerosolized Iloprost in Idiopathic Pulmonary Arterial Hypertension; PACES, The Efficacy and Safety of Sildenafil Citrate Used in Combination With Intravenous Epoprostenol in PAH; STEP, Iloprost Inhalation Solution Safety and Pilot Efficacy Trial in Combination with Bosentan for Evaluation in Pulmonary Arterial Hypertension; TRIUMPH I, Clinical Investigation Into Inhaled Treprostinil Sodium in Patients with Severe PAH

Data from Chin KM. Pulmonary arterial hypertension. J Am Coll Cardiol 2008;51:1527–1538 and Barst RJ, Gibbs JSR, Ghofrani HA, et al. Updated evidence-based treatment algorithm in pulmonary arterial hypertension. J Am Coll Cardiol 2009;54:S78–S84.

Investigational Therapy There are a few new agents within currently approved drug classes that are under investigation for use in PAH. Oral treprostinil is currently being evaluated in a series of studies known as the FREEDOM trials. FREEDOM-C (oral treprostinil in combination with an endothelin receptor antagonist and/or phosphodiesterase-5 inhibitor for the treatment of PAH) is a multicenter, randomized, double-blind trial evaluating oral treprostinil in patients already receiving an endothelin receptor antagonist and/or a phosphodiesterase-5 inhibitor. The trial found a nonsignificant improvement in 6-minute walk distance in patients on oral treprostinil for 16 weeks.[65] Macitentan, an ET_A/ET_B receptor antagonist, is under evaluation in a phase III trial (SERAPHIN).[20]

There are also novel pathways in the pathogenesis of PAH that may provide potential new targets for therapy. These include vasoactive intestinal polypeptide, Rho kinase inhibitors, serotonin receptor antagonists and transporter blockers, HMG-CoA reductase inhibitors, and platelet-derived growth factor.[17,20] Other strategies for PAH treatment include targeting angiogenesis, right ventricular remodeling, and endothelial progenitor cell therapy.[66]

EVALUATION OF THERAPEUTIC OUTCOMES

Response to treatment in PAH can be objectively measured by the 6-minute walk distance, echocardiography to assess pulmonary pressures, and right-heart catheterization as the gold standard to assess ventricular function and pulmonary pressures. The WHO functional classification system is clinically useful, but correlations to hemodynamics may be imprecise. Other outcomes that are useful in clinical trials include hospitalization for exacerbations of PAH and the development of complications and death.[67]

CLINICAL CONTROVERSY

The exact sequencing of drug therapy for PAH remains a matter of individual clinician preference given the paucity of randomized trial data to support selection of one drug over another in clinically worsening PAH. Of these sequencing dilemmas, the initiation of IV therapy is often the most controversial.

CONCLUSIONS

PAH is a challenging disease to manage; however, with the development of endothelin antagonists, phosphodiesterase inhibitors, and prostacyclin analogs, clinical improvement is possible in most patients, leading to a better quality of life and delay of disease progression. Patient education is important to improve acceptance of this disease and referral to specialty care centers that may provide the best outcomes.

ABBREVIATIONS

5-HTT: 5-hydroxytryptamine transporter
5-HT: serotonin
ALK-1: activin receptor-like kinase type 1
APAH: associated pulmonary arterial hypertension
BMPR2: bone morphogenetic protein receptor II
CCB: calcium channel blockers
CTEPH: chronic thromboembolic pulmonary hypertension
ec-NOS: nitric oxide synthase
FDA: Food and Drug Administration
FPAH: familial pulmonary arterial hypertension
HIV: human immunodeficiency virus
HPAH: heritable pulmonary arterial hypertension
IPAH: idiopathic pulmonary arterial hypertension
IV: intravenous
LVEDP: left ventricular end diastolic pressure
mPAP: mean pulmonary artery pressure
NO: nitric oxide
PAH: pulmonary arterial hypertension
PCH: pulmonary capillary hemangiomatosis
PVOD: pulmonary veno-occlusive disease
SC: subcutaneous

CHAPTER 36 Drug-Induced Pulmonary Diseases

HENGAMEH H. RAISSY, MICHELLE HARKINS, AND PATRICIA L. MARSHIK

KEY CONCEPTS

1. Select populations may be more susceptible to toxicities associated with specific agents.
2. Primary treatment is discontinuation of the offending agent and supportive care.

The manifestations of drug-induced pulmonary diseases span the entire spectrum of pathophysiologic conditions of the respiratory tract. As with most drug-induced diseases, the pathological changes are nonspecific. Therefore, the diagnosis is often difficult and, in most cases, is based on exclusion of all other possible causes. In addition, the true incidence of drug-induced pulmonary disease is difficult to assess as a result of the pathological nonspecificity and the interaction between the underlying disease state and the drugs.

Considering the physiologic and metabolic capacity of the lung, it is surprising that drug-induced pulmonary disease is not more common. The lung is the only organ of the body that receives the entire circulation. In addition, the lung contains a heterogeneous population of cells capable of various metabolic functions, including *N*-alkylation, *N*-dealkylation, *N*-oxidation, reduction of *N*-oxides, and *C*-hydroxylation.

Evaluation of epidemiologic studies on adverse drug reactions provides a perspective on the importance of drug-induced pulmonary disease. In a 2-year prospective survey of a community-based general practice, 41% of 817 patients experienced adverse drug reactions.[1] Four patients, or 0.5% of the total respondents, experienced adverse respiratory symptoms. Respiratory symptoms occurred in 1.2% of patients experiencing adverse drug reactions. In a recent retrospective analysis of clinical case series in France, 898 patients had reported drug allergy, with a bronchospasm incidence of 6.9%. When these patients were rechallenged with the suspected drug, only 241 (17.6%) tested positive. The incidence of bronchospasm in patients with positive provocation test was 7.9%.[2]

Adverse pulmonary reactions are uncommon in the general population but are among the most serious reactions, often requiring intervention. In a study of 270 adverse reactions leading to hospitalization from two populations, 3.0% were respiratory in nature.[3] Of the reactions considered to be life threatening, 12.3% were respiratory. An early report on death caused by drug reactions from the Boston Collaborative Drug Surveillance Program indicated that 7 of 27 drug-induced deaths were respiratory in nature.[4] This was confirmed in a follow-up study in which 6 of 24 drug-induced deaths were respiratory in nature.[5]

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

DRUG-INDUCED APNEA

Apnea may be induced by central nervous system depression or respiratory neuromuscular blockade (Table 36–1). Patients with chronic obstructive airway disease, alveolar hypoventilation, and chronic carbon dioxide retention have an exaggerated respiratory depressant response to narcotic analgesics and sedatives. In addition, the injudicious administration of oxygen in patients with carbon dioxide retention can worsen ventilation-perfusion mismatching, producing apnea.[6] Although the benzodiazepines are touted as causing less respiratory depression than barbiturates, they

may produce a profound additive or synergistic effect when taken in combination with other respiratory depressants. Combining intravenous diazepam with phenobarbital to stop seizures in an emergency department frequently results in admissions to an intensive care unit for a short period of assisted mechanical ventilation, regardless of the drug administration rate. Too rapid intravenous administration of any of the benzodiazepines, even without coadministration of other respiratory depressants, will result in apnea. The risk appears to be the same for the various available agents (diazepam, lorazepam, and midazolam). Respiratory depression and arrests resulting in death and hypoxic encephalopathy have occurred following rapid intravenous administration of midazolam for conscious sedation prior to medical procedures. 1 This has been reported more commonly in the elderly and the chronically debilitated or in combination with opioid analgesics. Concurrent use of inhibitors of cytochrome P450 3A4 with benzodiazepines is likely to lead to greater risk of respiratory depression.

1 Prolonged apnea may follow administration of any of the neuromuscular blocking agents used for surgery, particularly in patients with hepatic or renal dysfunction. In addition, persistent neuromuscular blockade and muscle weakness have been reported in critically ill patients who are receiving neuromuscular blockers continuously for more than 2 days to facilitate mechanical ventilation.[7] This has resulted in delayed weaning from mechanical ventilation and prolonged intensive care unit stays. The prolonged neuromuscular blockade has been confined principally to pancuronium and vecuronium in patients with renal disease. Both agents have pharmacologic active metabolites that are excreted renally. The persistent muscular weakness is less well defined but appears to represent an acute myopathy.[7] High-dose corticosteroids appear to produce a synergistic effect, supported by animal studies showing that corticosteroids at dosages ≥2 mg/kg per day of prednisone produce atrophy in denervated muscle.[8] The fluorinated corticosteroids (e.g., triamcinolone) appear to be more myopathic.[9] Dose-dependent respiratory muscle weakness has been reported in chronic obstructive pulmonary disease (COPD) and asthma patients receiving repeated short courses of oral prednisone in the previous 6 months.[10]

Respiratory failure has been known to occur following local spinal anesthesia. Apnea from respiratory paralysis and rapid respiratory muscle fatigue has followed the administration of polymyxin and aminoglycoside antibiotics.[6] The mechanism appears to be related to the complexation of calcium and its depletion at the myoneural junction. Intravenous calcium chloride has been variably effective in reversing the paralysis.[6] The aminoglycosides competitively block neuromuscular junctions. This has resulted in life-threatening apnea when neomycin, gentamicin, streptomycin, or bacitracin has been 1 administered into the peritoneal and pleural cavities.[6] The aminoglycosides will produce an additive blockade and ventilatory paralysis with curare or succinylcholine and in patients with myasthenia gravis or myasthenic syndromes.[6] Intravenous administration of aminoglycosides has resulted in respiratory failure in babies with infantile 2 botulism. Treatment consists of ventilatory support and administration of an anticholinesterase agent (neostigmine or edrophonium).[6]

DRUG-INDUCED ASTHMA

Epidemiologic studies demonstrate an increase in the prevalence of asthma and COPD with increased use of acetaminophen. The use of aspirin or ibuprofen is not associated with asthma or COPD.[11] The association between use of acetaminophen in infancy and childhood and risk of childhood asthma was reported by the International Study of Asthma and Allergies in Childhood, including data from 31 countries.[12] Administration of acetaminophen in the first year of life was associated with a 46% increase in risk of asthma symptoms at the age of 6 to 7 years.[12] These findings should be interpreted with caution since confounding by indication may play a part in this association. The acetaminophen—asthma/COPD association may be explained by reduction of glutathione, an endogenous antioxidant enzyme in the airway epithelium resulting in oxidant damage in the lung.[11]

DRUG-INDUCED BRONCHOSPASM

Bronchoconstriction is the most common drug-induced respiratory problem. Bronchospasm can be induced by a wide variety of drugs through a number of disparate pathophysiologic mechanisms (Table 36–2). Regardless of the pathophysiologic mechanism, drug-induced bronchospasm is almost exclusively a problem of patients with preexisting bronchial hyperreactivity (e.g., asthma, COPD).[13] By definition, all patients with nonspecific bronchial hyperreactivity will experience bronchospasm if given sufficiently high doses of cholinergic or anticholinesterase agents. Severe asthmatics with a high degree of bronchial reactivity may wheeze following the inhalation of a number of particulate substances, such as the lactose in dry-powder inhalers and inhaled corticosteroids, presumably through direct stimulation of the central airway irritant receptors. Other pharmacologic mechanisms for inducing bronchospasm include β_2-receptor blockade and nonimmunologic histamine release from mast cells and basophils.[13] A large number of agents are capable of producing bronchospasm through immunoglobulin (Ig)E-mediated reactions.[13] These drugs can become a significant occupational hazard for pharmacists, nurses, and pharmaceutical industry workers.[13]

ASPIRIN-INDUCED BRONCHOSPASM

Aspirin sensitivity or intolerance occurs in 4% to 20% of all asthmatics.[14] The frequency of aspirin-induced bronchospasm increases with age. Patients older than age 40 years have a frequency approximately four times that of patients younger than 20 years.[14] The frequency increases to 14% to 23% in patients with nasal polyps.[14] Women predominate over men, and there is no evidence for a genetic or familial predisposition.[15,16] The classic description of the aspirin-intolerant asthmatic includes the triad of severe asthma, nasal polyps, and aspirin intolerance. The typical patient experiences intense vasomotor rhinitis, which may or may not be associated with aspirin exposure, beginning during the third or fourth decade of life.[17] Over a period of months, nasal polyps begin to appear, followed by severe asthma exacerbated by aspirin. Bronchospasm typically begins within minutes to hours following ingestion of aspirin and is associated with rhinorrhea, flushing of the head and neck, and conjunctivitis.[17] The reactions are severe and often life threatening.

All aspirin-sensitive asthmatics do not fit the classic "aspirin triad" picture, and not all patients with asthma and nasal polyps develop sensitivity to aspirin.[15,16] In most cases, aspirin-sensitive asthmatics are clinically indistinguishable from the general population of asthmatics except for their intolerance to aspirin and other nonsteroidal antiinflammatory drugs (NSAIDs). Aspirin-induced asthmatics are not at higher risk of having fatal asthma if aspirin and other NSAIDs are avoided.[18]

Diagnosis of aspirin-induced asthma requires a detailed medical history. The definitive diagnosis is made by aspirin provocation tests, which may be done via different routes.[15,16,19] An oral provocation test is used commonly where threshold doses of aspirin induce a positive

reaction measured by a drop in forced expiratory volume in the first second of expiration (FEV_1) and/or the presence of symptoms.[19,20] A nasal provocation test is done by the application of one dose of lysine-aspirin, and aspirin sensitivity is manifested with clinical symptoms of watery discharge and a significant fall in inspiratory nasal flow.[19,20]

[a]A very small percentage (5%) of aspirin-sensitive patients react to acetaminophen and phenacetin.

When lysine-aspirin bronchoprovocation was compared with oral aspirin provocation, both methods were equally sensitive.[21]

PATHOGENESIS

Aspirin-induced asthma is correctly classified as an idiosyncratic reaction in that the pathogenesis is still unknown. Patients with aspirin intolerance have increased plasma histamine concentrations after ingestion of aspirin and elevated peripheral eosinophil counts.[15,17] All attempts to define an immunologic mechanism have been unsuccessful. Chemically similar drugs such as salicylamide and choline salicylate do not cross-react, whereas a large number of chemically dissimilar NSAIDs do produce reactions.[15,17] Table 36–3 lists the analgesics that do and do not cross-react with aspirin.

The currently accepted hypothesis of aspirin-induced asthma is that aspirin intolerance is integrally related to inhibition of cyclooxygenase. This is supported by the following evidence: (a) All NSAIDs that inhibit cyclooxygenase produce reactions, (b) the degree of cross-reactivity is proportional to the potency of cyclooxygenase inhibition, and (c) each patient with aspirin sensitivity has a threshold dose for precipitating bronchospasm that is specific for the degree of cyclooxygenase inhibition produced, and once established, the dose of another cyclooxygenase inhibitor needed to induce bronchospasm can be estimated.[17]

The mechanism by which cyclooxygenase inhibition produces bronchospasm in susceptible individuals is unknown. Arachidonic acid metabolism through the 5-lipoxygenase pathway may lead to the excess production of leukotrienes C_4 and D_4.[16,18] Leukotrienes C_4, D_4, and E_4 produce bronchospasm and promote histamine release from mast cells.[17] The precise mechanism by which augmented leukotriene production occurs is unknown, and available hypotheses do not explain why only a small number of asthmatic patients react to aspirin and NSAIDs.

DESENSITIZATION

Patients with aspirin sensitivity can be desensitized. The ease of desensitization correlates with the sensitivity of the patient.[17] Highly sensitive patients who react initially to less than 100 mg aspirin require multiple rechallenges to produce desensitization.[15] Desensitization

usually persists for 2 to 5 days following discontinuance, with full sensitivity reestablished within 7 days.[15] Cross-desensitization has been established between aspirin and all NSAIDs tested to date. Because patients may experience life-threatening reactions, desensitization should be attempted only in a controlled environment by personnel with expertise in handling these patients. In addition, there are reports of patients who have failed to maintain a desensitized state despite continued aspirin administration.[15,16] In one open follow-up trial in 172 aspirin-sensitive asthmatics who had undergone desensitization and continued daily aspirin treatment (1,300 mg/day) an improvement in nasal-sinus and asthma symptoms occurred after 6 months of treatment, which persisted up to 5 years.[22]

CROSS-SENSITIVITY WITH FOOD AND DRUG ADDITIVES

1 Up to 80% of aspirin-sensitive asthmatics will have an adverse reaction to the yellow azo dye tartrazine (FD&C Yellow No. 5), which is used widely for coloring foods, drinks, drugs, and cosmetics.[14] However, the studies reporting high cross-reactivity were poorly controlled and often used only subjective criteria.[14,23] In double-blind, placebo-controlled trials using pulmonary function testing, sensitivity to tartrazine has proved to be a rare event.[23] Tartrazine sensitivity appears to occur only in aspirin-intolerant patients at a prevalence of 2%.[23] Although rare, owing to the severity of reaction and widespread use of tartrazine, the U.S. Food and Drug Administration (FDA) requires labeling for the products containing this dye.[24] The likely mechanism is dose-related histamine release, and the clinical presentation is the same as the reaction to aspirin in aspirin-sensitive patients.[24]

Reactions to other azo dyes, monosodium glutamate, parabens, and nonazo dyes have been reported much less frequently than reactions to tartrazine and have been equally difficult to confirm with controlled challenges.[23] Positive reactions to sodium benzoate, a food preservative, have been reported in as many as 23% of aspirin-sensitive individuals.[14] Acetaminophen is a weak inhibitor of cyclooxygenase. As such, approximately 5% of aspirin-sensitive asthmatics will experience reactions to acetaminophen.[14] Most aspirin-sensitive asthmatics can use acetaminophen as a safe alternative to aspirin. There is a growing body of evidence that selective cyclooxygenase-2 inhibitors may be used safely in aspirin-sensitive patients,[16,25–28] but long-term studies with these agents should be undertaken to confirm their safe use in aspirin-sensitive patients. At this point, the package inserts of these agents state that they are contraindicated for aspirin-sensitive asthmatics.[16,25–28] Sporadic cases of worsening bronchospasm and anaphylaxis have been reported in aspirin-sensitive asthmatics receiving intravenous hydrocortisone succinate, but such reactions have not been reported with use of other corticosteroids.[15] It is not known whether it is the hydrocortisone or the succinate that is the problem.

TREATMENT

Aspirin-Sensitive Asthma

2 Therapy of aspirin-sensitive asthmatics takes one of two general approaches: desensitization or avoidance. Avoidance of triggering substances seldom alters the clinical course of patients' asthma. The therapy of asthma has been nonspecific; however, in theory, 5-lipoxygenase inhibitors such as zileuton or leukotriene antagonists should provide specific therapy. A few studies have investigated use of leukotriene modifiers to prevent aspirin-induced bronchospasm in aspirin-sensitive asthmatic patients.[29–33] Pretreatment with zileuton in eight aspirin-sensitive asthmatic patients protected them from the same threshold-provoking doses of aspirin.[29] However, larger, escalating doses of aspirin above the threshold challenge doses were not examined in this study. Furthermore, when doses of aspirin were escalated above the threshold provocative doses, zileuton did not prevent formation of leukotrienes.[30] In a similar study, pretreatment with montelukast 10 mg/day did not protect patients when aspirin doses were increased above their threshold doses.[31] In another study, the mean provoking dose of aspirin did not differ in the asthmatics who were taking leukotriene modifiers and the control group (60.4 mg vs. 70.3 mg, respectively).[34] Although initial studies suggested that leukotriene modifiers blocked aspirin-induced reactions, it is now apparent that they merely shift the dose—response curve to the right, leaving the patient at risk at higher doses. Thus even patients who might benefit from leukotriene modifiers should avoid aspirin and all NSAIDs. A case of ibuprofen 400-mg—induced asthma was reported in an asthmatic patient on zafirlukast 20 mg twice daily.[35] Furthermore, most of the challenge studies are based on incremental doses of aspirin or NSAIDs, and exposure of patients to full clinical doses of aspirin or NSAIDs can overcome the antagonistic effect of leukotriene modifiers. The respiratory symptoms can be decreased but not prevented by pretreatment with antihistamines, cromolyn, and nedocromil.[15,36] The long-term asthma control of patients with aspirin sensitivity does not differ from that for other asthmatics. There is no evidence to support that aspirin-sensitive asthmatics respond better to leukotriene modifiers. In a double-blind, randomized, placebo-controlled study, aspirin-sensitive asthmatic patients on montelukast showed a 10% improvement in FEV_1 compared with the placebo group.[37] Similar results were reported when montelukast was compared with placebo in patients with intermittent or persistent asthma.[38]

β-BLOCKERS

1 β-Adrenergic receptor blockers comprise the other large class of drugs that can be hazardous to a person with asthma. Even the more cardioselective agents such as acebutolol, atenolol, and metoprolol have been reported to cause asthma attacks.[13] Patients with asthma may take nonselective and β_1-selective blockers without incident for long periods; however, the occasional report of fatal asthma attacks resistant to therapy with β-agonists should provide ample warning of the dangers inherent in β-blocker therapy.[13]

If a patient with bronchial hyperreactivity requires β-blocker therapy, one of theselective β_1-blockers (e.g., acebutolol, atenolol, metoprolol, or pindolol) should be used at the lowest possible dose. In a meta-analysis of 29 clinical trials in patients with mild to moderate airway obstruction, cardioselective β-blockers did not produce any clinically significant respiratory effects in short term.[39] Celiprolol and betaxolol appear to possess greater cardioselectivity than currently marketed drugs.[40,41] Fatal status asthmaticus has occurred with the topical administration of the nonselective timolol maleate ophthalmic solution for the treatment of open-angle glaucoma.[42] Early investigations with ophthalmic betaxolol suggest that it is well tolerated even in timolol-sensitive asthmatics.[43,44]

SULFITES

Severe, life-threatening asthmatic reactions following consumption of restaurant meals and wine have occurred secondary to ingestion of the food preservative potassium metabisulfite.[23] Sulfites have been used for centuries as preservatives in wine and food. As antioxidants, they prevent fermentation of wine and discoloration of fruits and vegetables caused by contaminating bacteria.[45] Previously, sulfites had been given "generally recognized as safe"

status by the FDA. Sensitive patients react to concentrations ranging from 5 to 100 mg, amounts that are consumed routinely by anyone eating in restaurants. Consumption of sulfites in U.S. diets is estimated to be 2 to 3 mg/day in the home with 5 to 10 mg per 30 mL of beer or wine consumed.[23] Anaphylactic or anaphylactoid reactions to sulfites in nonasthmatics are extremely rare. In the general asthmatic population, reactions to sulfites are 1 uncommon. Approximately 5% of steroid-dependent asthmatics demonstrate sensitivity to sulfiting agents, but the prevalence is only around 1% in non—steroid-dependent asthmatic patients.[45]

MECHANISM

Three different mechanisms have been proposed to explain the reaction to sulfites in asthmatic patients.[45] The first is explained by the inhalation of sulfur dioxide, which produces bronchoconstriction in all asthmatics through direct stimulation of afferent parasympathetic irritant receptors. Furthermore, inhalation of atropine or the ingestion of doxepin protects sulfite-sensitive patients from reacting to the ingestion of sulfites. The second theory, IgE-mediated reaction, is supported by reported cases of sulfite-sensitive anaphylaxis reaction in patients with positive sulfite skin test. Finally, a reduced concentration of sulfite oxidase enzyme (the enzyme that catalyzes oxidation of sulfites to sulfates) compared with normal individuals has been demonstrated in a group of sulfite-sensitive asthmatics.

A number of pharmacologic agents contain sulfites as preservatives and antioxidants. The FDA now requires warning labels on drugs containing sulfites. Most manufacturers of drugs for the treatment of asthma have discontinued the use of sulfites. In addition, labeling is required on packaged foods that contain sulfites at 10 parts per million or more, and sulfiting agents are no longer allowed on fresh fruits and vegetables (excluding potatoes) intended for sale.

Pretreatment with cromolyn, anticholinergics, and cyanocobalamin have protected sulfite-sensitive patients.[45,46] Presumably, pharmacologic doses of vitamin B_{12} catalyze the nonenzymatic oxidation of sulfite to sulfate.

OTHER PRESERVATIVES

Both ethylenediamine tetraacetic acid (EDTA) and benzalkonium chloride, used as stabilizingand bacteriostatic agents, respectively, can produce bronchoconstriction.[47] In addition to producing bronchoconstriction, EDTA potentiates the bronchial responsiveness to histamine.[47] These effects presumably are mediated through calcium chelation by EDTA. Benzalkonium chloride is more potent than EDTA, and its mechanism appears to be a result of mast cell degranulation and stimulation of irritant C fibers in the airways.[47]

The bronchoconstriction from benzalkonium chloride can be blocked by cromolyn but not the anticholinergic ipratropium bromide.[48] Benzalkonium chloride is found in the commercial multiple-dose nebulizer preparations of ipratropium bromide and beclomethasone dipropionate marketed in the United Kingdom and Europe and is presumed to be in part responsible for paradoxical wheezing following administration of these agents.[47–49] Benzalkonium chloride is also found in albuterol nebulizer solutions marketed in the United States and has been implicated as a possible cause of paradoxical wheezing in infants receiving this preparation.[47] The effect of these agents on FEV_1 when used in the amount administered for treatment of acute asthma was evaluated in subjects with stable asthma.[50] Patients were assigned randomly to inhale up to four 600-mcg nebulized doses of EDTA and benzalkonium chloride and normal saline. The change in FEV_1 was not different between EDTA and the placebo group; however, benzalkonium chloride was associated with a statistically significant decrease in FEV_1 compared with placebo. It is important to consider that these agents are always used in combination with bronchodilators and β_2-agonists, which are potent mast cell stabilizers, and the anecdotal reports have not yet been confirmed with controlled investigations.[47,48]

CONTRAST MEDIA

Iodinated radiocontrast materials are the most common cause of anaphylactoid reactions producing bronchospasm.[51] Chapter 95 discusses this topic.

NATURAL RUBBER LATEX ALLERGY

Allergy to natural rubber latex, first reported in 1989 in the United States, is a common cause of occupational allergy for healthcare workers.[52] Natural rubber is a processed plant product from the commercial rubber tree, *Hevea brasiliensis*.[53] Latex allergens are proteins found in both raw latex and the extracts used in finished rubber products. Latex gloves are the largest single source of exposure to the protein allergens.[53]

1 The reported prevalence of latex allergy depends on the sample population. In the general population, latex allergy is less than 1%; however, the prevalence increases in healthcare workers to 5% to 15%.[53,54] Risk factors for latex allergy include frequent exposure to rubber gloves, history of atopic disease, and presence or history of hand dermatitis. Patients with spina bifida are at an increased risk of latex allergy, with an incidence of 24% to 60% as a result of early and repeated exposure to rubber devices during the surgical procedures.[53,54]

Clinical manifestations of latex allergy range from contact dermatitis and urticaria, rhinitis and asthma, and reported cases of anaphylaxis.[52,53] The early manifestation of rubber allergy is contact urticaria, which is an IgE-mediated reaction to rubber proteins following direct contact with the medical devices: mainly rubber gloves.[53] Contact dermatitis may occur within 1 to 2 days. Contact dermatitis is a cell-mediated delayed-type hypersensitivity reaction to the additive chemical component of rubber products.[53] Rhinitis and asthma may follow inhalation of allergens carried by cornstarch powder used to coat the latex gloves. Asthma caused by occupational exposure is seen mostly in atopic patients with histories of seasonal and perennial allergies and asthma.[53] Isolated cases of wheezing secondary to latex exposure in patients without a history of asthma have also been reported.[53]

The diagnosis of latex allergy is based on the presence of latex-specific IgE, as well as symptoms consistent with IgE-mediated 2 reactions.[55] The mainstay of therapy for latex allergy is avoidance. The FDA requires appropriate labeling for all medical devices containing natural rubber latex to ensure avoidance and a latex-free environment. The role of pretreatment with antihistamines, corticosteroids, and allergen immunotherapy remains to be determined.[53,55] Specific immunotherapy for latex allergy (either subcutaneous or sublingual immunotherapy) has been evaluated. However, the frequency and severity of side effects remain high so immunotherapy for patients with moderate to severe asthma is contraindicated .[54,56]

ANGIOTENSIN-CONVERTING ENZYME INHIBITOR–INDUCED COUGH

1 Cough has become a well-recognized side effect of angiotensin-converting enzyme (ACE) inhibitor therapy. According to spontaneous reporting by patients, cough occurs in 1% to 10% of patients

receiving ACE inhibitors, with a preponderance of females. In a retrospective analysis, 14.6% of women had cough compared with 6.0% of the men on ACE inhibitors. It is suggested that women have a lower cough threshold, resulting in their reporting this adverse effect more commonly than men.[57] Studies specifically evaluating cough caused by ACE inhibitors report a prevalence of 19% to 25%.[58,59] Patients receiving ACE inhibitors had a 2.3 times greater likelihood of developing cough than a similar group of patients receiving diuretics.[58] Patients with hyperreactive airways do not appear to be at greater risk.[58] African Americans and Chinese have a higher incidence of cough.[57] When different disease states were compared, 26% of patients with heart failure had ACE inhibitor—induced cough compared with 14% of those with hypertension.[57] Cough can occur with all ACE inhibitors.[60]

The cough is typically dry and nonproductive, persistent, and not paroxysmal.[60] The severity of cough varies from a "tickle" to a debilitating cough with insomnia and vomiting. The cough can begin within 3 days or have a delayed onset of up to 12 months following initiation of ACE inhibitor therapy.[60] The cough remits within 1 to 4 days of discontinuing therapy but (rarely) can last up to 4 weeks and recur with rechallenge.[60] Patients should be given a 4-day withdrawal to determine if the cough is induced by ACE inhibitors. The chest radiograph is normal, as are pulmonary function tests (spirometry and diffusing capacity). Bronchial hyperreactivity, as measured by histamine and methacholine provocation, may be worsened in patients with underlying bronchial hyperreactivity such as asthma and chronic bronchitis. However, bronchial hyperreactivity is not induced in others.[60,61] The cough reflex to capsaicin is enhanced but not to nebulized distilled water or citric acid.[60]

The mechanism of ACE inhibitor—induced cough is still unknown. ACE is a nonspecific enzyme that also catalyzes the hydrolysis of bradykinin and substance P (see Chap. 19) that produce or facilitate inflammation and stimulate lung irritant receptors.[60] ACE inhibitors may also induce cyclooxygenase to cause the production of prostaglandins. NSAIDs, benzonatate, inhaled bupivacaine, theophylline, baclofen, thromboxane A_2 synthase inhibitor,[57,62] and cromolyn sodium all have been used to suppress or inhibit ACE inhibitor—induced cough.[60,63] The cough is generally unresponsive to cough suppressants or bronchodilator therapy. No long-term trials evaluating different treatment options for ACE inhibitor—induced cough exist. Cromolyn sodium may be considered first because it is the 2 most studied agent and has minimal toxicity.[57] The preferred therapy is withdrawal of the ACE inhibitor and replacement with an alternative antihypertensive agent. Owing to their decrease in ACE inhibitor—induced side effects, angiotensin II receptor antagonists are often recommended in place of an ACE inhibitor; however, there are rare reports of this agent inducing bronchospasm.[64] The clinical trials suggest that angiotensin II receptor antagonists have the same incidence of cough as placebo. Furthermore, when angiotensin II receptor antagonists were compared with ACE inhibitors, cough occurred much less frequently. Reduction in the incidence of cough with angiotensin II receptor antagonists is likely caused by the lack of effect on clearance of bradykinin and substance P.[65] The use of alternative therapies to treat ACE inhibitor—induced cough is generally not recommended.[60]

PULMONARY EDEMA

Pulmonary edema may result from the failure of any of a number of homeostatic mechanisms. The most common cause of pulmonary edema is an increase in capillary hydrostatic pressure because of left ventricular failure. Excessive fluid administration in compensated and decompensated heart failure patients is the most frequent cause of iatrogenic pulmonary edema. Besides hydrostatic forces, other homeostatic mechanisms that may be disrupted include the osmotic and oncotic pressures in the vasculature, the integrity of the alveolar epithelium, the interstitial pulmonary pressure, and the interstitial lymph flow.[6] The edema fluid in cardiogenic pulmonary edema contains a low amount of protein, whereas noncardiogenic pulmonary edema fluid has a high protein concentration.[6] This indicates that noncardiogenic pulmonary edema results primarily from disruption of the alveolar epithelium.

The clinical presentation of pulmonary edema includes persistent cough, tachypnea, dyspnea, tachycardia, rales on auscultation, hypoxemia from ventilation—perfusion imbalance and intrapulmonary shunting, widespread fluffy infiltrates on chest roentgenogram, and decreased lung compliance (stiff lungs). Noncardiogenic pulmonary edema may progress to hemorrhage; cellular debris collects in the alveoli, followed by hyperplasia and fibrosis with a residual restrictive mechanical defect.[6,66]

NARCOTIC-INDUCED PULMONARY EDEMA

The most common drug-induced noncardiogenic pulmonary edema is produced by the narcotic analgesics (Table 36–4).[6] Narcotic-induced pulmonary edema is associated most commonly with intravenous heroin use but also has occurred with morphine,

methadone, meperidine, and propoxyphene use.[6,66,67] There have also been a few reported cases associated with the use of the opiate antagonist naloxone and nalmefene, a long-acting opioid antagonist.[66,68,69] The mechanism is unknown but may be related to hypoxemia similar to the neurogenic pulmonary edema associated with cerebral tumors or trauma or a direct toxic effect on the alveolar capillary membrane.[67] Initially thought to occur only with overdoses, most evidence now supports the theory that narcotic-induced pulmonary edema is an idiosyncratic reaction to moderate as well as high narcotic doses.[66,67]

Patients with pulmonary edema may be comatose with depressed respirations or dyspnea and tachypnea. They may or may not have other signs of narcotic overdose. Symptomatology varies from cough and mild crepitations on auscultation with characteristic radiologic findings to severe cyanosis and hypoxemia, even with supplemental oxygen. Symptoms may appear within minutes of intravenous administration but may take up to 2 hours to occur, particularly following oral methadone.[67] Hemodynamic studies in the first 24 hours have demonstrated normal pulmonary capillary wedge pressures in the presence of pulmonary edema.

Clinical symptoms generally improve within 24 to 48 hours, and radiologic clearing occurs in 2 to 5 days, but abnormalities in pulmonary function tests may persist for 10 to 12 weeks. Therapy consists of naloxone administration, supplemental oxygen, and ventilatory support if required. Mortality is less than 1%.[67]

Cough has been reported with intravenous administration of fentanyl.[70] A cohort of 1,311 adult patients undergoing elective surgery had 120 patients with vigorous cough within 20 seconds after administration of fentanyl.[70] The cough was associated with young age and absence of cigarette smoking.[70] Among anesthetic factors, it was associated with the absence of epidurally administered lidocaine and the absence of a priming dose of vecuronium.[70] A history of asthma or COPD had no predictive effect.[70] Further clinical trials are required to understand the mechanism of paradoxical cough with fentanyl and to identify the means to prevent it.

OTHER DRUGS THAT CAUSE PULMONARY EDEMA

A paradoxical pulmonary edema has been reported in a few patients following hydrochlorothiazide ingestion but not any other thiazide diuretic.[6] Acute pulmonary edema rarely has followed the injection of high concentrations of contrast medium into the pulmonary circulation during angiocardiography.[6] Rare occurrences of pulmonary edema have followed the intravenous administration of bleomycin, cyclophosphamide, and vinblastine.[6]

The selective β_2-adrenergic agonists terbutaline and ritodrine have been reported to induce pulmonary edema when used as tocolytics.[6] This disorder commonly occurs 48 to 72 hours after tocolytic therapy.[69] This has never occurred with their use in asthma patients, even in inadvertent overdosage. This reaction may result from excess fluid administration used to prevent the hypotension from β_2-mediated vasodilation or the particular hemodynamics of pregnancy. In a review of 330 patients who received tocolytic therapy and were monitored closely for their fluid status, no episode of pulmonary edema was reported.[69]

Interleukin-2, a cytokine used alone or in combination with cytotoxic drugs, has been reported to induce pulmonary edema. Although other cytokines have been associated with pulmonary edema, the problem is most significant with interleukin-2. A weight gain of 2 kg has been reported after treatment with interleukin-2.[69]

Pulmonary edema has occurred occasionally with salicylate overdoses. The serum salicylate concentrations are often greater than 45 mg/dL, and the patients have other signs of toxicity, although some cases have been associated with concentrations in the usual therapeutic range.[66,67]

PULMONARY EOSINOPHILIA

Pulmonary infiltrates with eosinophilia (Löffler syndrome) are associated with nitrofurantoin, *para*-aminosalicylic acid, methotrexate, sulfonamides, tetracycline, chlorpropamide, phenytoin, NSAIDs, and imipramine (Table 36–5).[6,71,72] The disorder is characterized by fever, nonproductive cough, dyspnea, cyanosis, bilateral pulmonary infiltrates, and eosinophilia in the blood.[6] Lung biopsy has revealed perivasculitis with infiltration of eosinophils, macrophages, and proteinaceous edema fluid in the alveoli. The symptoms and eosinophilia generally respond rapidly to withdrawal of the offending drug.

Sulfonamides were first reported as causative agents in users of sulfanilamide vaginal cream.[6] *para*-Aminosalicylic acid frequently produced the syndrome in tuberculosis patients being treated with this agent.[6] There are nine reported cases associated with sulfasalazine use in inflammatory bowel disease.[71] The drug associated most frequently with this syndrome is nitrofurantoin.[6,67] Nitrofurantoin-induced lung disorders appear to be more common in postmenopausal women.[67] Lung reactions made up 43% of 921 adverse reactions to nitrofurantoin reported to the Swedish Adverse Drug Reaction Committee between 1966 and 1976.[71] No apparent correlation exists between duration of drug exposure and severity or reversibility of the reaction.[71] Most cases occur within 1 month of therapy. Typical symptoms include fever, tachypnea, dyspnea, dry cough, and, less commonly, pleuritic chest pain. Radiographic findings include bilateral interstitial infiltrates, predominant in the bases and pleural effusions 25% of the time. Although there are anecdotal reports that steroids are beneficial, the usual rapid improvement following discontinuation of the drugs brings the usefulness of steroids into question. Complete recovery usually occurs within 15 days of withdrawal.

TABLE 36-5 Drugs That Induce Pulmonary Infiltrates with Eosinophilia (Löffler Syndrome)

Drug	Relative Frequency of Reactions	Drug	Relative Frequency of Reactions

F, frequent; I, infrequent; R, rare.

A few cases of pulmonary eosinophilia have been reported in asthmatics treated with cromolyn.[6,71] The significance of this is unknown in light of the occasional spontaneous occurrence of pulmonary eosinophilia in asthmatic patients. Cases of acute pneumonitis and eosinophilia have been reported to occur with phenytoin and carbamazepine therapy.[71] Patients have had other symptoms of hypersensitivity, including fever and rashes. The symptoms of dyspnea and cough subside following discontinuation of the drug.

OXYGEN TOXICITY

Because of the similarity to pulmonary fibrosis, oxygen-induced lung toxicity is reviewed briefly. More extensive reviews on this topic have been published.[73,74]

The earliest manifestation of oxygen toxicity is substernal pleuritic pain from tracheobronchitis.[74] The onset of toxicity follows an asymptomatic period and presents as cough, chest pain, and dyspnea. Early symptoms are usually masked in ventilator-dependent patients. The first noted physiologic change is a decrease in pulmonary compliance caused by reversible atelectasis. Then decreases in vital capacity occur, followed by progressive abnormalities in carbon monoxide diffusing capacity.[74] Decreased inspiratory flow rates, reflected in the need for high inspiratory pressures in ventilator-dependent patients, occur as the fractional concentration of inspired oxygen requirement increases. The lungs become progressively stiffer as the ability to oxygenate becomes more compromised.

The fraction of inspired oxygen and duration of exposure are both important determinants of the severity of lung damage. Normal human volunteers can tolerate 100% oxygen at sea level for 24 to 48 hours with minimal to no damage.[73] Oxygen concentrations of less than 50% are well tolerated even for extended periods. Inspired oxygen concentrations between 50% and 100% carry a substantial risk of lung damage, and the duration required is inversely proportional to the fraction of inspired oxygen.[73] Underlying disease states may alter this relationship. Lung damage may not be lasting and may improve months to years after the exposure.[75,76]

Oxygen-induced lung damage is generally separated into the acute exudative phase and the subacute or chronic proliferative phase. The acute phase consists of perivascular, peribronchiolar, interstitial, and alveolar edema with alveolar hemorrhage and necrosis of pulmonary endothelium and type I epithelial cells.[73] The proliferative phase consists of resorption of the exudates and hyperplasia of interstitial and type II alveolar lining cells. Collagen and elastin deposition in the interstitium of alveolar walls then leads to thickening of the gas-exchange area and the fibrosis.[73]

The biochemical mechanism of the tissue damage during hyperoxia is the increased production of highly reactive, partially reduced oxygen metabolites (Fig. 36–1).[74] These oxidants are normally produced in small quantities during cellular respiration and include the superoxide anion, hydrogen peroxide, the hydroxyl radical, singlet oxygen, and hypochlorous acid.[74] Oxygen free radicals are normally formed in phagocytic cells to kill invading microorganisms, but they are also toxic to normal cell components. The oxidants produce toxicity through destructive redox reactions with protein sulfhydryl groups, membrane lipids, and nucleic acids.[74]

The oxidants are products of normal cellular respiration that are normally counterbalanced by an antioxidant defense system that prevents tissue destruction. The antioxidants include superoxide dismutase, catalase, glutathione peroxidase, ceruloplasmin, and α-tocopherol (vitamin E). Antioxidants are ubiquitous in the body. Hyperoxia produces toxicity by overwhelming the antioxidant system. There is experimental evidence that a number of drugs and chemicals produce lung toxicity through increasing production of oxidants (e.g., bleomycin, cyclophosphamide, nitrofurantoin, and paraquat) and/or by inhibiting the antioxidant system (e.g., carmustine, cyclophosphamide, and nitrofurantoin).[77,78]

PULMONARY FIBROSIS

A large number of drugs are associated with chronic pulmonary fibrosis with or without a preceding acute pneumonitis (Table 36–6). The cancer chemotherapeutic agents make up the largest group and have been the subject of numerous reviews.[77,78]

TABLE 36-6 Drugs That Induce Pneumonitis and/or Fibrosis

Drug	Relative Frequency of Reactions	Drug	Relative Frequency of Reactions
Oxygen	F	Chlorambucil	R
Radiation	F	Melphalan	R
Bleomycin	F	Lomustine and semustine	R
Busulfan	F	Zinostatin	R
Carmustine	F	Procarbazine	R
Hexamethonium	F	Teniposide	R
Paraquat	F	Sulfasalazine	R
Amiodarone	F	Phenytoin	R
Mecamylamine	I	Gold salts	R
Pentolinium	I	Pindolol	R
Cyclophosphamide	I	Imipramine	R
Practolol	I	Penicillamine	R
Methotrexate	I	Phenylbutazone	R
Mitomycin	I	Chlorphentermine	R
Nitrofurantoin	I	Fenfluramine	R
Methysergide	I	Leflunomide	R
Sirolimus	I	Mefloquine	R
Azathioprine, 6-mercaptopurine	R	Pergolide	R

F, frequent; I, infrequent; R, rare.

Although the mechanisms by which all the drugs produce pneumonitis and fibrosis are not known, the clinical syndrome, pulmonary function abnormalities, and histopathology present a relatively homogeneous pattern.[77] The histopathological picture closely resembles oxidant lung damage, and in some experimental cases, oxygen enhances the pulmonary injury.[67] Although the terms *pulmonary fibrosis* or *interstitial pneumonitis* have been used widely to describe pneumonia after bone marrow transplantation, in 1991, a National Institutes of Health workshop recommended that the term *idiopathic pneumonia syndrome* (IPS) should be used to avoid histopathological terms and to define the inherent heterogeneity of this disorder.[79] IPS accounts for more than 40% of deaths related to bone marrow transplantation.[79] Suggested causes of IPS include radiation or chemotherapy regimens prior to transplantation, graft-versus-host disease, unrecognized infections, and other inflammation-related lung injuries.[80,81] IPS is characterized by dyspnea, hypoxemia, nonproductive cough, diffuse alveolar damage, and interstitial pneumonitis in the absence of lower respiratory infection. IPS has been reported early and late, up to 24 months after bone marrow transplantation.[81]

The lung damage following ingestion of the contact herbicide paraquat classically resembles hyperoxic lung damage. Hyperoxia accelerates the lung damage induced by paraquat. Lung toxicity from paraquat occurs following oral administration in humans and aerosol administration and inhalation in experimental animals.[78] The pulmonary specificity of paraquat results in part from its active uptake into lung tissue. Paraquat readily accepts an electron from reduced nicotinamide-adenine dinucleotide phosphate and then is reoxidized rapidly, forming superoxide and other oxygen radicals.[78] The toxicity may be a result of nicotinamide-adenine dinucleotide phosphate depletion (see Fig. 36–1) and/or excess oxygen free radical generation with lipid peroxidation. Treatment with exogenous superoxide dismutase has had limited and conflicting results.[78]

A number of furans have been shown to produce oxidant injury to lungs.[78] Occasionally, patients with acute nitrofurantoin lung toxicity will progress to a chronic reaction leading to fibrosis, and rarely, a patient may develop chronic toxicity without an antecedent acute reaction. Like paraquat, nitrofurantoin undergoes cyclic reduction and reoxidation that may produce superoxide radicals or deplete nicotinamide-adenine dinucleotide phosphate. In addition, nitrofurantoin inhibits glutathione reductase, an enzyme involved in the glutathione antioxidant system (see Fig. 36–1). Table 36–7 lists possible nondrug causes of pulmonary fibrosis.

TABLE 36-7 Possible Causes of Pulmonary Fibrosis

Idiopathic pulmonary fibrosis (fibrosing alveolitis)
Pneumoconiosis (asbestosis, silicosis, coal dust, talc berylliosis)
Hypersensitivity pneumonitis (molds, bacteria, animal proteins, toluene diisocyanate, epoxy resins)
Smoking
Sarcoidosis
Tuberculosis
Lipoid pneumonia
Systemic lupus erythematosus
Rheumatoid arthritis
Systemic sclerosis
Polymyositis/dermatomyositis
Sjögren syndrome
Polyarteritis nodosa
Wegener granuloma

Siderosis (arc welders' lung)
Radiation
Oxygen
Chemicals (thioureas, trialkylphosphorothioates, furans)
Drugs (see Tables 36–5, 36–6, and 36–8)

DRUGS ASSOCIATED WITH PULMONARY FIBROSIS

ANTINEOPLASTICS

A number of cancer chemotherapeutic agents produce pulmonary fibrosis. In an excellent review,[77] six predisposing factors for the development of cytotoxic drug—induced pulmonary disease were described: (a) cumulative dose, (b) increased age, (c) concurrent or previous radiotherapy, (d) oxygen therapy, (e) other cytotoxic drug therapy, and (f) preexisting pulmonary disease. Drugs that are directly toxic to the lung would be expected to show a dose—response relationship. Dose—response relationships have been established for bleomycin, busulfan, and carmustine (BCNU).[77] Bleomycin and busulfan exhibit threshold cumulative doses below which a very small percentage of patients exhibit toxicity, but carmustine shows a more linear relationship.[78] Older patients appear to be more susceptible, possibly as a result of a decrease in the antioxidant defense system.

Excessive irradiation produces a pneumonitis and fibrosis thought to be caused by oxygen free radical formation.[77] Evidence for synergistic toxicity with radiation exists for bleomycin, busulfan, and mitomycin.[77] Hyperoxia has shown synergistic toxicity with bleomycin, cyclophosphamide, and mitomycin.[77] Carmustine, mitomycin, cyclophosphamide, bleomycin, and methotrexate all appear to show increased lung toxicity when they are part of multiple-drug regimens.

NITROSOUREAS

BCNU is associated with the highest incidence of pulmonary toxicity (20% to 30%).[77] The lung pathology generally resembles that produced by bleomycin and busulfan. Unique to BCNU is the finding of fibrosis in the absence of inflammatory infiltrates. BCNU preferentially inhibits glutathione reductase, the enzyme required to regenerate glutathione, thus reducing glutathione tissue stores.[77,78] The patients present with dyspnea, tachypnea, and nonproductive cough that may begin within a month of initiation of therapy but may not develop for as long as 3 years.[77] Most patients receiving BCNU develop fibrosis that may remain asymptomatic or become symptomatic any time up to 17 years after therapy.[82] The cumulative dose has ranged from 580 to 2,100 mg/m^2.[78] The disease is usually slowly progressive with a mortality rate from 15% to greater than 90% depending on the study and period of follow-up. In a retrospective study, the risk factors for development of IPS and prognostic factors for outcomes were evaluated in 94 patients with relapsed Hodgkin disease treated with BCNU containing high-dose chemotherapy and hematopoietic support. The risk factors for pulmonary fibrosis and mortality were female sex and dose of BCNU, with all deaths reported in those who received BCNU at doses of more than 475 mg/m^2.[83] Rapid progression and death within a few days occur in a small percentage of patients.[77] Corticosteroids do not appear to be effective in reducing damage.[77] Other nitrosoureas, lomustine, and semustine have also been reported to produce lung damage in patients receiving unusually high doses.[77]

BLEOMYCIN

Bleomycin is the best-studied cytotoxic pulmonary toxin. Because of its lack of bone marrow suppression, pulmonary toxicity is the dose-limiting toxicity of bleomycin therapy. The incidence of bleomycin lung toxicity is approximately 4%, which may be

affected by the following risk factors: bleomycin cumulative dose, age, high concentration of inspired oxygen, radiation therapy, and multidrug regimens, particularly those with cyclophosphamide.[69] Age at the time of treatment with bleomycin may also be a risk factor; patients younger than 7 years of age at the time of receiving bleomycin therapy are more likely to develop pulmonary toxicity compared with older subjects.[69] The cumulative dose above which the incidence of toxicity significantly increases is 450 to 500 units.[77] However, rapidly fatal pulmonary toxicity has occurred with doses as low as 100 units.[77]

Experimentally, bleomycin generates superoxide anions, and the lung toxicity is increased by radiation and hyperoxia.[77] Pretreatment with superoxide dismutase and catalase reduces toxicity in experimental animals.[77] Bleomycin also oxidizes arachidonic acid, which may account for the marked inflammation. Bleomycin may also affect collagen deposition by its stimulation of fibroblast growth.[77] Combination of bleomycin with other cytotoxic agents, particularly regimens containing cyclophosphamide, may predispose patients to pulmonary damage.

There are two distinct clinical patterns of bleomycin pulmonary toxicity. Chronic progressive fibrosis is the most common; acute hypersensitivity reactions occur infrequently. Patients present with cough and dyspnea. The first physiologic abnormality seen is a decreased diffusing capacity of carbon monoxide.[77] Chest radiographs show a bibasilar reticular pattern, and gallium scans show marked uptake in the involved lung.[77] Chest radiographic changes lag behind pulmonary function abnormalities. Spirometry tests before each bleomycin dose are not predictive of toxicity. The single-breath diffusing capacity of carbon monoxide is the most sensitive indicator of bleomycin-induced lung disease. Although it is not absolutely predictive, a drop of 20% or greater in the diffusing capacity of carbon monoxide is an indication for using alternative therapies.[77] The prognosis of bleomycin lung toxicity has improved as a consequence of early detection, but the mortality rate is approximately 25%. Mild cases respond to discontinuation of bleomycin therapy.[69] Corticosteroid therapy appears to be helpful in patients with acute pneumonitis, although there have been no controlled trials. Patients with chronic fibrosis are less likely to respond. Although corticosteroids have been used for a number of drug-induced pulmonary problems, a study in mice showing a potential for worsening of lung damage when administered early during the repair stage should sound a word of caution against their indiscriminate use.[84]

MITOMYCIN

Mitomycin is an alkylating antibiotic that produces pulmonary fibrosis at a frequency of 3% to 12%.[77] The mechanism is unknown, but oxygen and radiation therapy appear to enhance the development of toxicity.[77] The clinical presentation and symptoms are the same as for bleomycin. The mortality rate is approximately 50%. Early withdrawal of the drug and administration of corticosteroids appear to improve the outcome significantly.

ALKYLATING AGENTS

A number of alkylating agents are associated with pulmonary fibrosis (see Table 36–5). The incidence of clinical toxicity is around 4%, although subclinical damage is apparent in up to 46% of patients at autopsy. The mechanism of toxicity is unknown; however, epithelial cell damage that triggers the arachidonic acid inflammatory cascade may be the initiating event.[77] The clinical presentation is insidious, with 4 years being the average durationof therapy before the onset of symptoms.[77] Patients present with low-grade fever, weight loss, weakness, dyspnea, cough, and rales.[77] Pulmonary function tests initially show abnormal diffusion capacity followed by a restrictive pattern (low vital capacity). The histopathologic findings are nonspecific. The prognosis is one of slow progression with a mean survival of 5 months following diagnosis.[77] Although there is no direct dose-dependent correlation, patients receiving less than 500 mg of busulfan do not develop the syndrome without concomitant radiation or use of other pulmonary toxic chemotherapeutic agents.[77] There are anecdotal reports of beneficial responses to corticosteroids, but no controlled studies have been done.

Cyclophosphamide infrequently produces pulmonary toxicity. More than 20 well-documented cases have been reported to date. In animal models, cyclophosphamide produces reactive oxygen radicals. High oxygen concentrations produce synergistic toxicity with cyclophosphamide. The duration of therapy before the onset of symptoms is highly variable, and there may be a delay of several months between the onset of symptoms and discontinuation of the drug.[77] Cyclophosphamide may potentiate carmustine lung toxicity.[77] Clinical symptoms usually consist of dyspnea on exertion, cough, and fever. Inspiratory crackles and the bibasilar reticular pattern typical of cytotoxic drug-induced radiographic changes are present. Histopathological changes are also nonspecific. Approximately 60% of patients recover. Corticosteroid therapy has been reported to be beneficial; however, death despite corticosteroid administration has also been reported.

Chlorambucil, melphalan, and uracil mustard are also associated with pulmonary fibrosis. Of the alkylating agents, only nitrogen mustard and thiotepa have not been reported to cause fibrotic pulmonary toxicity.[77]

ANTIMETABOLITES

Methotrexate was first reported to induce pulmonary toxicity in 1969.[77] The pulmonary toxicity to methotrexate is unique in that discontinuation is not always necessary, and reinstitution of the drug may not produce recurrence of symptoms.[6] Methotrexate pulmonary toxicity most commonly appears to result from hypersensitivity,[71] and it can occur 3 or more years following methotrexate therapy.[85] Age, sex, underlying pulmonary disease, duration of therapy, or smoking is not associated with an increased risk of pneumonitis with methotrexate.[85] Serial pulmonary function tests did not help to identify pneumonitis in patients receiving methotrexate before the onset of clinical symptoms.[85] Reductions in diffusing capacity of carbon monoxide and lung volumes are the most common manifestations of methotrexate lung toxicity.[69] Pulmonary edema and eosinophilia are common, and fibrosis occurs in only 10% of the patients who develop acute pneumonitis.[77] Systemic symptoms of chills, fever, and malaise are common before the onset of dyspnea, cough, and acute pleuritic chest pain. Methotrexate is also associated with granuloma formation.[77]

The prognosis of methotrexate-induced pulmonary toxicity is good, with a 1% or less mortality rate.[71] Pulmonary toxicity has followed intrathecal as well as oral administration and has occurred after single doses as well as long-term daily and intermittent administration.[77] Pneumonitis has been reported to occur up to 4 weeks following discontinuation of therapy.[77] Numerous anecdotal reports have claimed dramatic benefit from corticosteroid therapy. It is unknown whether intermittent (weekly) dosing, as is done for rheumatoid arthritis, decreases the risk of methotrexate-induced pulmonary toxicity because pneumonitis has occurred with this form of dosing.

Rarely, azathioprine and its major metabolite 6-mercaptopurine have been reported to produce an acute restrictive lung disease. Procarbazine, a methylhydrazine associated more commonly with Löffler syndrome, rarely has been associated with pulmonary fibrosis.[71] The vinca alkaloids vinblastine and vindesine have been

reported to produce severe respiratory toxicity in association with mitomycin. The incidence with the combination is 39% and may represent a true synergistic effect between these agents.[77]

NONCYTOTOXIC DRUGS

Pulmonary fibrosis associated with the ganglionic-blocking agent hexamethonium was first reported in 1954 (see Table 36–6).[6] Patients developed extreme dyspnea after several months on the drug. Pathological findings were consistent with bronchiectasis, bronchiolectasis, and fibrosis.[6] This phenomenon has occurred occasionally with use of the other ganglionic blockers (i.e., mecamylamine and pentolinium).[6]

In 1959, radiographic changes characteristic of diffuse pulmonary fibrosis were reported in 27 (87%) of 31 patients who had taken phenytoin for 2 years or more.[67] Since then, studies have been conflicting. If phenytoin does produce chronic fibrosis, it would appear to be a relatively rare event.

Gold salts (sodium aurothiomalate) used in the treatment of rheumatoid arthritis have produced pulmonary fibrosis with cough, dyspnea, and pleuritic pain 5 to 16 weeks following institution of therapy.[67] Pulmonary function tests show a restrictive defect, and patients generally have an eosinophilia. The reactions improve on discontinuation of the gold therapy and recur promptly on reexposure. The pulmonary deficit may not resolve completely.

AMIODARONE

Amiodarone, a benzofuran derivative, produces pulmonary fibrosis when used for supraventricular and ventricular arrhythmias (see Table 36–6).[86] The duration of amiodarone therapy before the onset of symptoms has ranged from 4 weeks to 6 years.[67,86,87] The estimated incidence is 1 in 1,000 to 2,000 treated patients per year. The clinical course is variable, ranging from acute onset of dyspnea with rapid progression into severe respiratory failure and death caused by slowly developing exertional dyspnea over a few months. Patients generally improve on discontinuation of the drug.[86,87] The majority of patients develop reactions while taking maintenance doses greater than 400 mg daily for more than 2 months or smaller doses for more than 2 years. The risk of amiodarone pulmonary toxicity is higher during the first 12 months of therapy even at a low dosage.[88] Other risk factors include cardiopulmonary surgery combined with the administration of high concentrations of oxygen.[88] Routine spirometry does not appear to be predictive of patients at risk.[89] Carbon monoxide diffusing capacity studies are sensitive indicators of amiodarone pulmonary toxicity but have only a 21% positive predictive value.[89] Clinical findings include exertional dyspnea, nonproductive cough, weight loss, and occasionally low-grade fever.[67,87,89] Radiographic changes are nondiagnostic and consist of diffuse bilateral interstitial changes consistent with a pneumonitis. Pulmonary function abnormalities include hypoxia, restrictive changes, and diffusion abnormalities.

The mechanism of amiodarone-induced pulmonary toxicity is multifactorial. Amiodarone and its metabolite can damage lung tissue directly by a cytotoxic process or indirectly by immunologic reactions.[88] Amiodarone is an amphiphilic molecule that contains both a highly apolar aromatic ring system and a polar side chain with a positively charged nitrogen atom.[86] Amphiphilic drugs characteristically produce a phospholipid storage disorder in the lungs of experimental animals and humans.[78] Chlorphentermine, an anorectic, is the prototype amphiphilic compound. The mechanism is currently believed to be the inhibition of lysosomal phospholipases.[78] The inflammation and fibrosis are thought to be a late finding resulting from nonspecific inflammation following the breakdown of phospholipid-laden macrophages.[86]

In a review of 39 cases, 9 patients died, and the remaining 30 patients had resolution of abnormalities after withdrawal of the drug.[86] Some patients have had resolution with lowering of the dosage, and therapy has been reinstituted at lower doses without problems in others. Of the patients who died, one half had received corticosteroids. There are reports of a protective effect with prophylactic corticosteroids and other reports of patients developing amiodarone lung toxicity while on corticosteroids.[86] At this time, any benefit of corticosteroids is unclear because most patients improve after stopping the drug.

MISCELLANEOUS PULMONARY TOXICITY

Drugs may produce serious pulmonary toxicity as part of a more generalized disorder. The pleural thickening, effusions, and fibrosis that occur as an extension of the retroperitoneal fibrotic reactions of methysergide and practolol or as part of a drug-induced lupus syndrome are the most common examples (Table 36–8).

Pleural and pulmonary fibrosis has been reported in one patient taking pindolol, a β-blocker structurally similar to practolol, an agent known to produce fibrosis.[67] Acute pleuritis with pleural effusions and fibrosis is a prominent manifestation of drug-induced lupus syndrome. Procainamide is associated with the largest number of pulmonary reactions, with 46% of patients with the lupus syndrome developing pulmonary complications.[6] Symptoms include pleuritic pain and fever with muscle and joint pain. Chest radiographs show bilateral pleural effusions and linear atelectasis. Patients have a positive antinuclear antibody test. Symptoms usually resolve within 6 weeks of drug withdrawal.[6]

Hydralazine is the next most common cause of lupus syndrome. Most patients who develop pleuropulmonary manifestations have antecedent symptoms of generalized lupus.[6] Other drugs that produce the lupus syndrome include isoniazid and phenytoin. Phenytoin can also produce hilar lymphadenopathy as part of a generalized pseudolymphoma or lymphadenopathy syndrome.[6]

TABLE 36-8 Drugs That May Induce Pleural Effusions and Fibrosis

	Relative Frequency of Reactions
Idiopathic	
Methysergide	F
Practolol	F

Tetracycline	R
Pseudolymphoma syndrome	
Cyclosporine	R
Phenytoin	R

F, frequent; I, infrequent; R, rare.

MONITORING THERAPEUTIC OUTCOMES

Monitoring for drug-induced pulmonary diseases consists primarily of having a high index of suspicion that a particular syndrome may be drug induced. Most hypersensitivity or allergic reactions (bronchospasm) occur rapidly, within the first 2 weeks of therapy with the offending agent, and reverse rapidly with appropriate therapy (e.g., withdrawal of the offending agent and administration of corticosteroids and bronchodilators). Dyspnea associated with Löffler syndrome and acute pulmonary edema syndromes also improve rapidly in 1 to 2 days. However, some residual defect in diffusion capacity and the roentgenogram may persist for a few weeks. It is probably unnecessary to do follow-up spirometry or diffusion capacity determinations in these patients unless there is some concern that the syndrome will progress to pulmonary fibrosis (through the use of bleomycin or nitrofurantoin).

The routine monitoring of patients receiving known pulmonary toxins with dose-dependent toxicity such as amiodarone, bleomycin, or carmustine is still controversial. For chronic fibrosis, the diffusing capacity of carbon monoxide is the most sensitive test and may be useful in patients receiving bleomycin for detecting and preventing further deterioration of lung function with continued administration. Carmustine lung toxicity may be delayed up to 10 years following administration, and routine monitoring has not proved preventive. Monitoring patients receiving amiodarone in doses greater than 400 mg/day every 4 to 6 months may prove useful in detecting early disease that requires lowering the amiodarone or stopping the drug. Because there is no evidence of a cumulative dose effect once it has been established that the patient can tolerate the elevated dose, continued routine monitoring past the first year is unnecessary.

ABBREVIATIONS

ACE: angiotensin-converting enzyme

COPD: chronic obstructive pulmonary disease

EDTA: ethylenediamine tetraacetic acid

FDA: Food and Drug Administration

FEV_1: forced expiratory volume in the first second of expiration

IPS: idiopathic pneumonia syndrome

NSAIDs: nonsteroidal antiinflammatory drugs

CHAPTER 37

Cystic Fibrosis

CHANIN C. WRIGHT AND YOLANDA Y. VERA

KEY CONCEPTS

1. Good nutrition with appropriate pancreatic enzyme and vitamin supplementation are essential in the management of cystic fibrosis.
2. Altered pharmacokinetics of cystic fibrosis patients can impact the dosing and clearance of pharmacologic therapy.
3. Airway clearance and antiinflammatory therapies are key components to improve pulmonary health in cystic fibrosis patients.
4. Antipseudomonal agents are the cornerstone of antibiotic therapy for chronic lung infections in the cystic fibrosis patient.

"Woe to that child which when kissed on the forehead tastes salty. He is bewitched and soon must die." This European adage accurately describes the fate of an individual diagnosed with cystic fibrosis during ancient times.[1]

Cystic fibrosis (CF) is a disease state resulting from a dysfunction in the cystic fibrosis transmembrane receptor (CFTR). It is the most common life-limiting disorder in the white population, with an incidence of 1 in 2,000 to 4,000 live births and a prevalence of 30,000 affected individuals in the United States.[2–7]

Currently with care, affected individuals have an expected life span of 36 years. Multiple organ systems are affected in CF individuals; especially, the lungs, the digestive system, and the reproductive organs. Mortality is most commonly due to chronic organ damage or resistant pulmonary infections.[8]

The pharmacist plays an essential role in the development and management of a pharmacotherapeutic care plan for the CF patient.

EPIDEMIOLOGY

CF is an autosomal recessive disease occurring in approximately 1 in 3,500 newborns. In the 1970s, patients only survived into their teen years. By 2006, progress in care had extended survival to 36 years. Institution of care at a young age impacts long-term survival; hence, timing of diagnosis and recognition of signs and symptoms is crucial.[2–7]

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

Although CF occurs in all ethnicities, other ethnicities besides the white population display lower frequencies: 1 in 9,200 Hispanic Americans, 1 in 10,900 Native Americans, 1 in 15,000 African Americans, and 1 in 31,000 Asians. The carrier frequency is 1 in 28 for North American white populations, 1 in 29 Ashkenazi Jews, and 1 in 60 African Americans.[2]

ETIOLOGY

The cause of CF is due to a mutation of the CFTR gene. Extensive genetic studies have increased awareness regarding the large spectrum of mutations in the CF population. Over 15,000 mutations have been identified, however, typical panels screen for only 30 of them. The most common mutation identified in CF patients is ΔF508.[3]

Cystic fibrosis is an autosomal recessive disease, in which one mutation present on each allele of the CFTR gene results in presentation of the disease. The presentation of a mutation on only one allele of the CFTR gene will prevent the full expression of CF. Genetic studies have increased the understanding of genotype—phenotype relationships. Various mutations on the CFTR gene can result in various pathologies from primary lung disease to minor gastrointestinal (GI) involvement.[3]

PATHOPHYSIOLOGY

In order to treat CF successfully, a good understanding of the disease's underlying mechanism of action is crucial. It is well established that gene mutations cause an abnormality in the cystic fibrosis transmembrane conductance regulator. This initiates the sequence of events responsible for the manifestations of CF. Mucosal obstruction occurs in the distal airways of the lung and submucosal glands, which express the CFTR. The CFTR also performs numerous cellular functions, including the regulation of chloride transport across the cell membrane. Studies in genotype—phenotype relationships have shown that an abnormality on the CFTR contributes to the expression of other gene proteins involved with inflammatory responses, ion transport, and cell signaling. These various expressions result in differences in clinical severity among patients with the same mutations on the CFTR.[3,9–11]

Under normal conditions, the CFTR helps regulate ion transport and salt homeostasis in the sweat glands. Normally, the sodium ion is followed by the chloride ion and is reabsorbed from the lumen by the CFTR and apical sodium channels. As a result of the CFTR's malfunction in CF patients, chloride fails to be reabsorbed, which impacts the sodium ion reabsorption as well. This failed process produces sweat that contains high levels of salt. The end point of this process is a highly negatively charged lumen, which leads to an increased salt content in the sweat gland. This is also known as the transepithelial potential difference, which is 2 to 3 times as great in CF patients, as

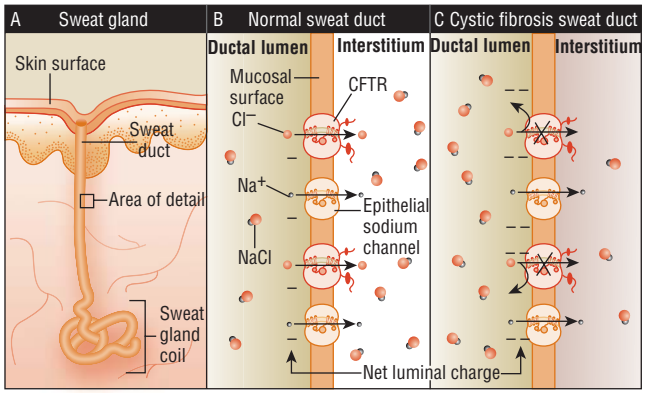

FIGURE 37-1. Mechanism of underlying elevated sodium chloride levels in the sweat of patients with cystic fibrosis. Sweat ducts (panel A) in patients with cystic fibrosis differ from those in people without the disease in the ability to reabsorb chloride before the emergence of sweat on the surface of the skin. A major pathway for Cl^- absorption is through CFTR, situated within luminal plasma membranes of cells lining the duct (i.e., on the apical, or mucosal, cell surface) (panel B). Diminished chloride reabsorption in the setting of continued sodium uptake leads to an elevated transepithelial potential difference across the wall of the sweat duct, and the lumen becomes more negatively charged because of a failure to reabsorb chloride (panel C). The result is that total sodium chloride flux is markedly decreased, leading to increased salt content. The thickness of the arrows corresponds to the degree of movement of ions.[10] *(Rowe SM, Miller S, Sorscher EJ. Cystic fibrosis. N Engl J Med 2005;352(19):1992–2001. Copyright © 2005 Massachusetts Medical Society. All rights reserved.)*

the potential difference in patients without the disease. These processes can lead to organ damage in the CF patient (Fig. 37–1).

There are several theories as to how mucosal obstruction occurs in the airways. One of these theories, known as the *low-volume model*, explains that the pulmonary surface epithelium behaves the opposite of a sweat gland in CF patients. There is an increased absorption of sodium, chloride, and fluid, which causes dehydration of the airway surfaces and defective mucociliary transport. An alternative theory known as the *high-salt model* indicates that the pulmonary surface epithelium behaves similarly to the sweat gland. A high salt content predisposes the CF patient to bacterial infections. Both theories agree that CF airways lack the ability to transport chloride through the CFTR.[9,12–13]

One of the common causes of morbidity and mortality in CF patients is mucosal obstruction of the exocrine glands. Mucosal obstruction causes the ducts to dilate, which results in the coating of lung surfaces by thick, viscous, neutrophil-dominated debris. These secretions initiate a cascade of events that lead to inflammation and formation of scar tissue in the lungs[14] (Fig. 37–2).

Other organ systems are impacted by the absence of CFTR activity as well. Ten percent of CF patients are born with meconium ileus, which is an intestinal obstruction that may be fatal if left untreated. Blockage of the pancreatic duct leads to complications such as chronic fibrosis and fatty replacement of the pancreatic gland. Bile duct obstruction causes cirrhosis of the liver, and CF male patients can experience infertility due to obstruction of the vas deferens in utero.[9]

CLINICAL PRESENTATION

In the classic presentation of CF, there are two mutations present (Table 37–1). The patients show signs and symptoms of chronic sinus and pulmonary infections, pancreatic insufficiency, and elevated sweat chloride levels. Patients with nonclassic CF have one mutation present, therefore retaining partial function of the CFTR and maintaining appropriate pancreatic function. (Fig. 37–3.)

SINUS AND PULMONARY PRESENTATION

CF patients will usually experience chronic infections and frequently develop polyps in the sinus cavity. Daily symptomatology includes shortness of breath and cough, with sputum production. A common finding in radiology chest films is a flat diaphragm with an increased chest diameter and air trapping. Pulmonary function tests will reflect a decrease in forced expiratory volume in 1 second (FEV_1). Older patients will experience digital clubbing, a deformity of the fingers and fingernails often associated with chronic hypoxia.

Bacterial growth in the lungs will often drive CF patients to a state of exacerbation, resulting in increased cough, a reduction in pulmonary function, and increased sputum production with a change in color.

GASTROINTESTINAL SYSTEM PRESENTATION

Newborns may present with meconium ileus, which is considered diagnostic of CF. Infants and small children will show an increase in frequency of small stools. Typically, steatorrhea, or greasy stools, is present and can lead to a failure to thrive, resulting in malnutrition. Older patients may experience constipation, abdominal cramping, and flatulence. This presentation is due to the obstruction of the pancreatic ducts and intestinal tract and their inability to digest essential nutrients. Patients with nonclassic CF will mostly maintain adequate pancreatic function and the ability to digest and absorb nutrients.

Pancreatic malfunction can also lead to an insulin deficiency, which is often a later finding detected by a loss in weight, an increase in blood glucose levels, and a failed oral glucose tolerance test (OGTT).

REPRODUCTIVE PRESENTATION

As patients reach adolescent and adult ages, tests may show azoospermia due to blockage of or the congenital bilateral absence of the vas deferens. Females may experience reduced fertility as cervical fluids have lower water content and decreased thinning during ovulation.[9,15–16]

DIAGNOSIS

CF newborn screening is required in all states as of 2010.[17] Depending on the state, this may include immunoreactive trypsin (IRT) screening and/or DNA analysis for genetic mutations. Abnormal values are followed up with sweat testing. The *quantitative pilocarpine iontophoresis sweat test* (QPIT) came about due to the risk of hyperpyrexia associated with older methods that utilized plastic body bags to make patients sweat. QPIT uses only a small area on the forearm, which is then stimulated to secrete sweat through the skin by iontophoresis of pilocarpine. Sweat from the stimulated area is then collected and analyzed for chloride content. Chloride concentrations are quantified as: normal: ≤39 mmol/L; intermediate: 40 to 59 mmol/L; abnormal: ≥60 mmol/L. Values ≥60 mmol/L are consistently diagnostic of CF. It is suggested that samples from two sites will increase the reliability of the diagnosis[3,7] (Fig. 37–4).

DESIRED OUTCOMES

Pharmacists play a vital role in assisting patients to reach the following goals, both long-term and short-term. Since CF affects multiple

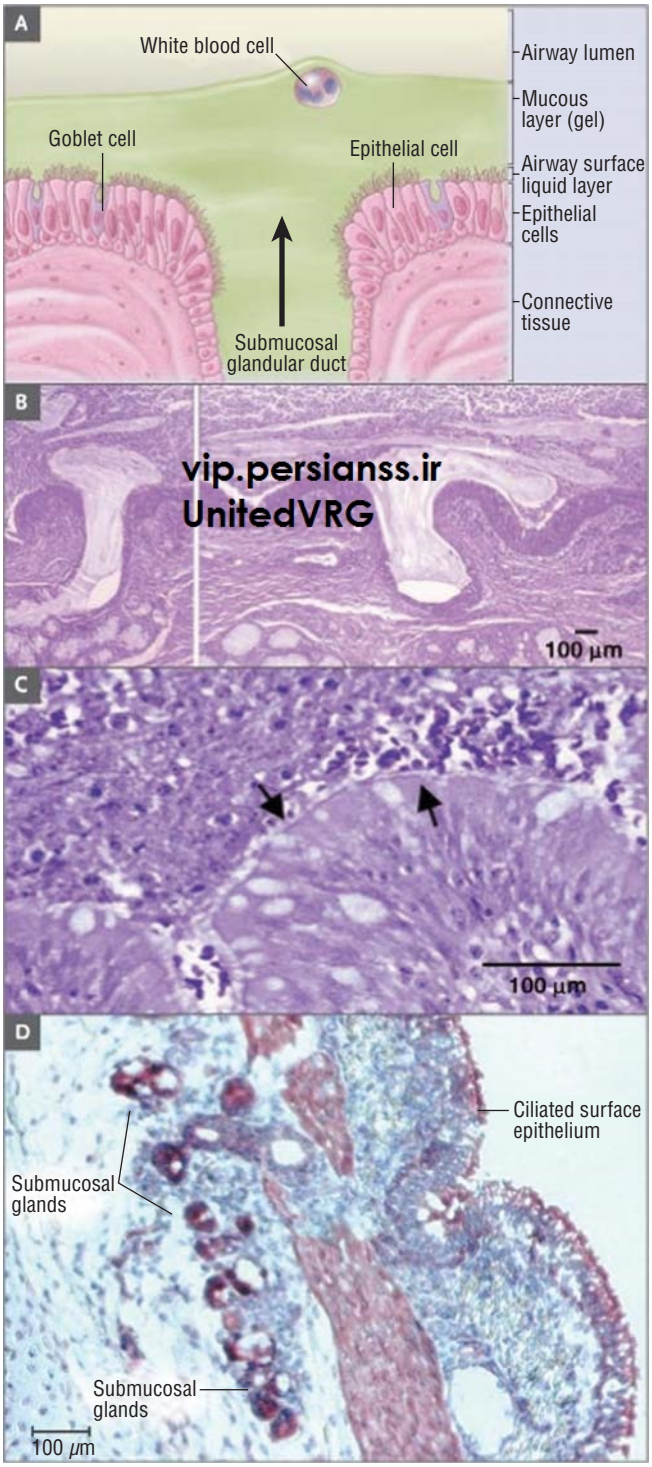

FIGURE 37-2. Extrusion of mucus secretion onto the epithelial surface of airways in cystic fibrosis. Panel A shows a schematic of the surface epithelium and supporting glandular structure of the human airway. In panel B, the submucosal glands of a patient with cystic fibrosis are filled with mucus, and mucopurulent debris overlies the airway surfaces, essentially burying the epithelium. Panel C is a higher-magnification view of a mucus plug tightly adhering to the airway surface, with arrows indicating the interface between infected and inflamed secretions and the underlying epithelium to which the secretions adhere. (Both panels B and C were stained with hematoxylin and eosin, with the colors modified to highlight structures.) Infected secretions obstruct airways and, over time, dramatically disrupt the normal architecture of the lung. In panel D, CFTR is expressed in surface epithelium and serous cells at the base of submucosal glands in a porcine lung sample, as shown by the dark staining, signifying binding by CFTR antibodies to epithelial structures (aminoethylcarbazole detection of horseradish peroxidase with hematoxylin counterstain).[10] (*Rowe SM, Miller S, Sorscher EJ. Cystic fibrosis. N Engl J Med 2005;352(19):1992–2001. Copyright © 2005 Massachusetts Medical Society. All rights reserved.*)

organ systems, there are several therapeutic goals that must be addressed for each system.[8]

SINOPULMONARY

- Prevent and treat sinusitis.
- Increase FEV_1 and promote optimal pulmonary function tests and prevent pulmonary exacerbations.
  - Promote effective airway clearance by providing counseling on use of appropriate medications and chest physiotherapy.
  - Prevent and treat colonization of the lungs with pathogens.
  - Prevent and treat acute exacerbations.

GASTROINTESTINAL

- Control pancreatic insufficiency by providing adequate enzyme supplementation.
- Optimize growth and nutritional status.
- Promote healthy bowel habits.
- Maintain normal vitamin levels.

REPRODUCTION

- Provide mutation analysis with appropriate genetic counseling at the time of diagnosis and periodically thereafter.

TABLE 37-1 Cystic Fibrosis Foundation Diagnosis Criteria and Clinical Presentation

A. Meets one or more of the following clinical features associated with the CF phenotype plus:
  a. Two CF mutations
  b. Two positive QPIT results
  c. An abnormal transepithelial potential difference value
B. The following are typical phenotypes associated with CF:
  a. Chronic sinopulmonary disease
    i. Persistent colonization/infection with pathogens typical of CF lung disease
    ii. Endobronchial disease manifested by
      1. Cough and sputum production
      2. Wheeze and air trapping
      3. Radiographic abnormalities
      4. Evidence of obstruction on pulmonary function test
      5. Digital clubbing
    iii. Chronic sinus disease
      1. Nasal polyps
      2. Radiographic changes
  b. Gastrointestinal/nutritional abnormalities
    i. Intestinal abnormalities
      1. Meconium ileus
      2. Exocrine pancreatic insufficiency
      3. Distal intestinal obstruction syndrome
      4. Rectal prolapse
      5. Recurrent pancreatitis
    ii. Chronic hepatobiliary disease manifested by clinical and/or laboratory evidence of
      1. Focal biliary cirrhosis
      2. Multilobar cirrohosis
    iii. Failure to thrive
    iv. Hypoproteinemia-edema
    v. Fat-soluble vitamin deficiencies
  c. Obstructive azoospermia in males
  d. Salt-loss syndromes
    i. Acute salt depletion
    ii. Chronic metabolic alkalosis
  e. CF in a first degree relative

PSYCHOSOCIAL

- Advocate activity in school and the workplace.
- Encourage compliance with pharmacologic and nonpharmacologic therapies in order to help prolong CF patient's lives.

NUTRITION

1 In healthy individuals, the pancreas is vital to the absorption and digestion of essential nutrients for the body's growth and function. In pancreatic-insufficient CF individuals, the resulting inability to absorb these nutrients may lead to malnourishment. The focus of treatment lies in achieving and maintaining normal weight for adults and normal growth patterns for children. This is mostly achieved by managing GI and pulmonary symptoms, monitoring nutrient and energy intakes, and addressing psychosocial and financial issues. Numerous population-based studies have provided strong evidence to support optimization of nutritional status, due to its association with an improved pulmonary status. The Cystic Fibrosis Foundation, therefore, recommends that both children and adults maintain normal nutritional status in an effort to promote, healthy pulmonary function, including a better FEV_1 and an increase in survival.

To help meet this desired outcome, the Cystic Fibrosis Foundation recommends energy intakes greater than the standard for the general population to support weight gain and maintenance in children over 2 years and in adults. Trial evidence gathered from population-based studies has shown that energy intakes of 110% to 200% compared to the general health population intakes yield improved nutritional status in CF individuals. The Cystic Fibrosis Foundation has also established consensus-based assessment parameters to monitor nutritional status in CF individuals. These parameters and goals are listed under Table 37–2. In order to achieve these goals, pancreatic enzyme replacement therapy (PERT) is utilized to improve fat absorption due to pancreatic insufficiency. For patients who consistently fail to meet weight requirements, the clinician must consider the use of nutritional supplements that may be given orally or enterally via a percutaneous endoscopic gastrostomy tube (PEG).

PERT has been proven both safe and efficacious in improving nutritional status in CF patients and is recommended in addition to adequate dietary intake. Consensus-based guidelines have established a dose of 500 to 2,500 lipase units/kg of body weight per meal; or 10,000 units/kg/day; or 4,000 units/g of dietary fat per day. Generic enzyme supplements are not bioequivalent; therefore, the Cystic Fibrosis Foundation does not recommend their use.

Until recently, pancreatic enzymes were considered nutritional supplements and were not under the Food and Drug Administration (FDA) jurisdiction. New regulations required all pancreatic enzymes to obtain FDA approval by April 28th, 2010. To date, Creon®, and Zenpep®, and Pancreaze™ have been the only FDA approved preparations. Table 37–3 shows currently used enzyme preparations.[18–39]

Most preparations are capsules containing enteric-coated microspheres or enteric-coated tablets designed to withstand the acidic environment in the stomach allowing for absorption in the small intestine. Frequently CF patients require the addition of histamine receptor antagonists or proton pump inhibitors in order to create an alkaline environment in the intestine. Enteric-coated capsules should not be crushed but may be opened and mixed with nonalkaline food. However, if allowed to sit in food for a prolonged amount of time, the enteric coating will be lost and enzymes will be inactivated. Enzymes are administered prior to meals and snacks.[40]

Patients dosed beyond the recommended guidelines may develop fibrosing colonopathy, which leads to colonic strictures. This condition should be considered for individuals who have evidence of obstruction, bloody diarrhea, or ascites, as well as for patients who have a combination of abdominal pain, ongoing diarrhea and/or poor weight gain. Risk factors for fibrosing colonopathy include: age <12 years; enzyme dosage >6,000 lipase units/kg/meal for more than 6 months; history of meconium ileus or distal intestinal obstruction syndrome (DIOS); history of any intestinal surgery; and inflammatory bowel disease.

Patients who experience fibrosing colonopathy are treated by reducing the dose of enzyme supplements, or with oral laxatives and/or enemas, all of which have been proven effective. More severe cases may require surgical intervention.[41]

BONE HEALTH AND VITAMIN SUPPLEMENTATION

Increased longevity in CF patients has revealed bone disease as an emerging complication. Many studies have observed that 50% to 75% of CF adults have low bone density and increased rates of fractures. CF patients are especially at risk as a result of several contributing factors: malabsorption of vitamin D, poor nutritional status, physical inactivity, glucocorticoid therapy, delayed pubertal maturation, and early hypogonadism. Increased bone resorption and decreased bone formation are likely stimulated by elevated serum cytokine levels triggered by chronic pulmonary inflammation. Additionally, chronic infections lead to bone loss in patients

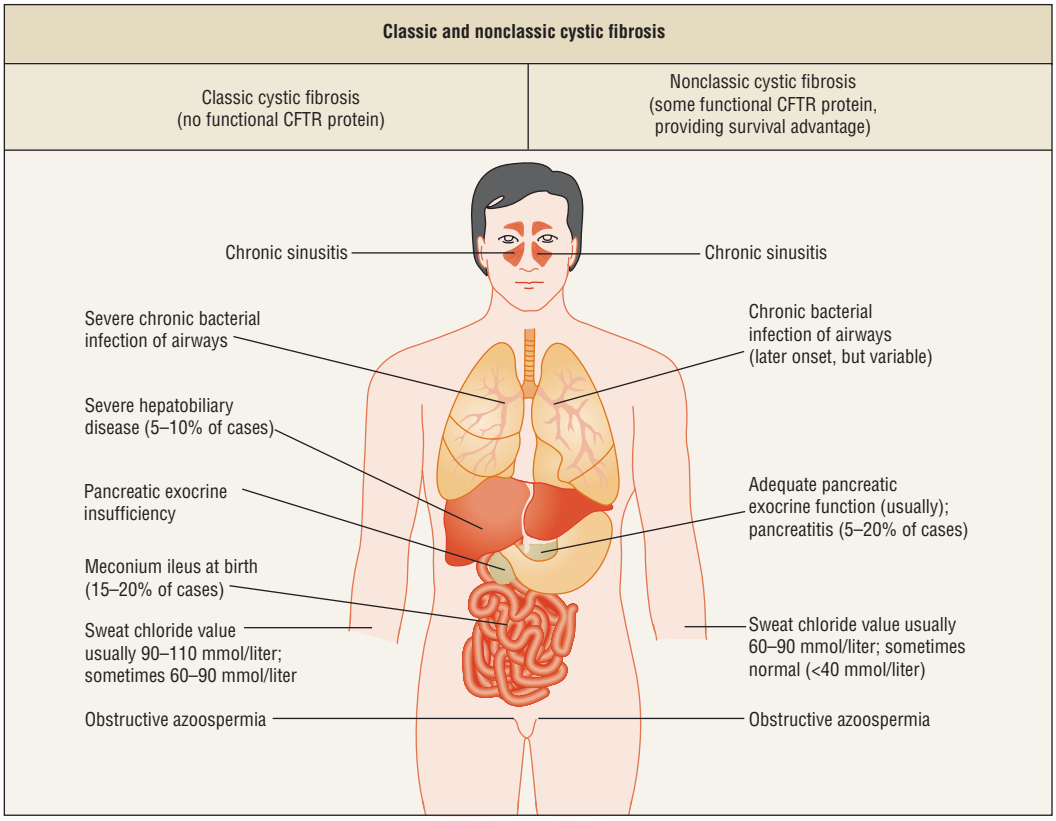

FIGURE 37-3. Classic and nonclassic cystic fibrosis. The findings in classic cystic fibrosis are shown on the left-hand side, and those of nonclassic cystic fibrosis on the right-hand side. Patients with nonclassic cystic fibrosis have better nutritional status and better overall survival. Although the lung disease is variable, patients with nonclassic cystic fibrosis usually have late-onset or more slowly progressive lung disease. Sweat-gland function, as evidenced by the sweat chloride test, is abnormal but not to the extent noted in classic cystic fibrosis. Pancreatitis may occur in patients with nonclassic disease. However, chronic sinusitis and obstructive azoospermia occur in both groups of patients. On the basis of these findings, one can infer that mutations in CTFR, perhaps coupled with other genetic or environmental factors, may confer a predisposition to sinusitis, pancreatitis, or congenital bilateral absence of the vas deferens (azoospermia) in the general population.[16] *(Knowles MR, Durie PR. What is cystic fibrosis? N Engl J Med 2002;347(6):439–442. Copyright © 2002 Massachusetts Medical Society. All rights reserved.)*

regardless of pancreatic sufficiency. Pancreatic insufficient CF patients have the inability to absorb fat-soluble vitamins A, D, E, and K. Decreased calcium absorption and intake can also compound this problem. As bone disease progresses, this can lead to exclusion from lung transplantation, which is often a life-saving operation for individuals with CF.

Appropriate bone density monitoring for CF patients requires a bone density scan in addition to obtaining levels of fat-soluble vitamins periodically. Special multivitamin formulations contain high amounts of fat-soluble vitamins designed to deliver the appropriate doses required. Even with these precautions, adequate vitamin D levels may be difficult to maintain due to altered absorption, reduced fat mass, and minimal exposure to sunlight. Medical management of CF patients can also contribute to bone disease by the administration of glucocorticoids, post-transplant immunosuppressant therapies, and antibiotic therapies that require protection from sunlight exposure.[42–50]

PULMONARY HEALTH AND TREATMENT

3 One of the fundamentals of pulmonary care in CF patients is airway clearance. CF patients, in general, have impaired mucociliary clearance that results in thick sputum, predisposing them to chronic infections and inflammation. Effective airway clearance involves the use of a bronchodilator, a mucolytic medication, and chest percussion. It is recommended that airway clearance therapy (ACT) be initiated within the first few months of life Table 37–4).

Choosing a particular ACT routine for a patient is based on the patient's needs. There is no consensus on the optimal method of ACT. The regimen, including duration or number of treatments per day may be changed in response to acute illness or exacerbations.

Chest percussion was originally performed by hand, with a cupped hand pounding on the chest, which generates percussion or vibration. Currently, the most convenient method is the use of a percussion vest. Aerobic exercise is also effective and recommended for improved airway clearance.[51]

The recommended sequence of clearance therapy or "pulmonary toilet" regimen is as follows (note that these therapies are recommended for individuals ≥6 years of age and are administered concurrently with percussion therapy):

1. Bronchodilator: Albuterol is commonly used for this indication. It helps open up the airways and prevents bronchospasm.
2. Hypertonic saline (HyperSal™): It hydrates the airway mucus secretions and facilitates mucociliary function.
3. Dornase alfa (Pulmozyme®): Enzyme that cleaves extracellular DNA, which results in decreased viscosity of mucus.
4. Aerosolized antibiotics [tobramycin (TOBI®)]: If this therapy is indicated based on severity of lung disease and sputum cultures, it is administered after the CF patient completes percussion therapy.

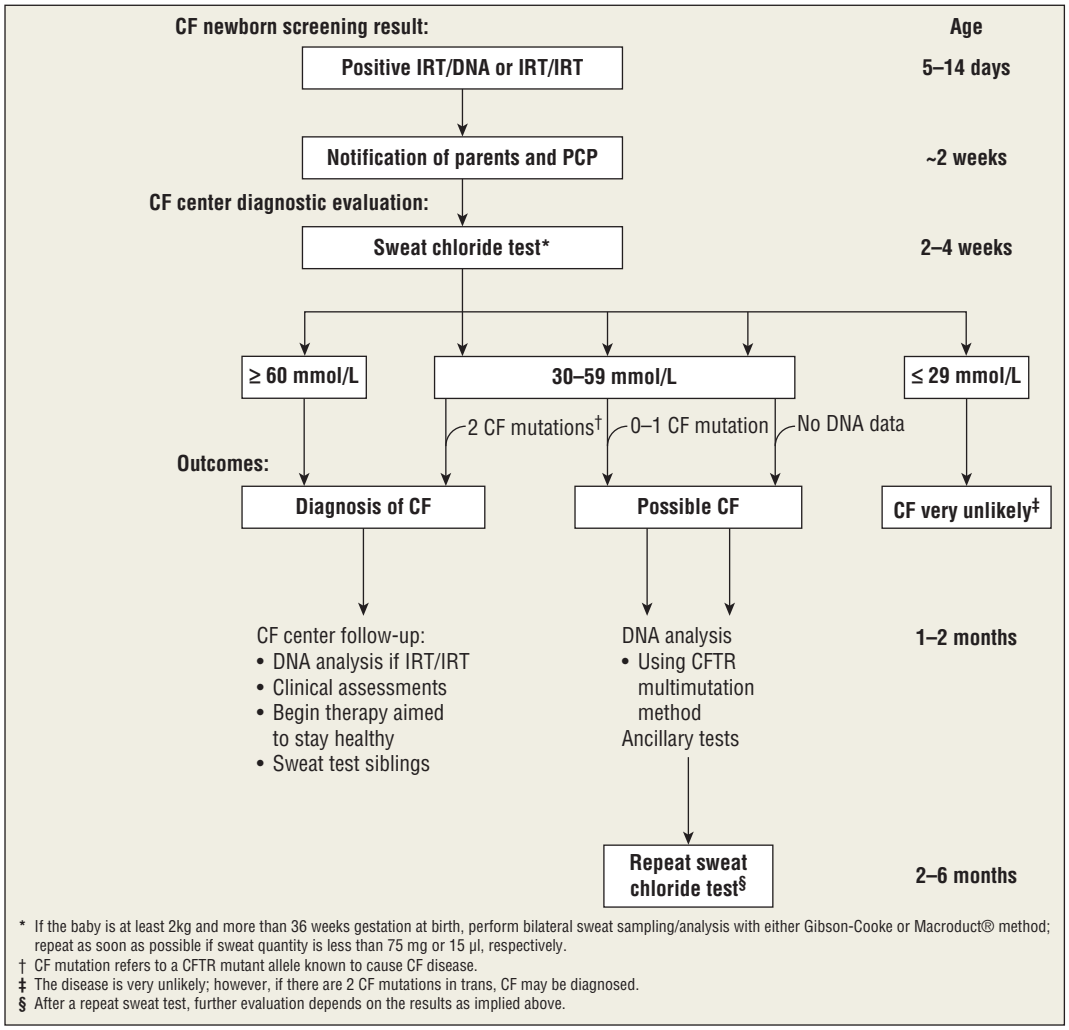

FIGURE 37-4. The CF diagnostic process for screened newborns.[3] (*Reprinted from J Pediatr, Vol. 153(2), Farrell PM, Rosenstein BJ, White TB, et al. Guidelines for the diagnosis of cystic fibrosis in newborns through older adults: Cystic Fibrosis Foundation Consensus Report, pages S4–14, Copyright © 2008, with permission from Elsevier.)*

Bronchodilator therapy is recommended for patients ≥6 years of age who demonstrate bronchiole hyperresponsiveness or a bronchodilator response. Chronic use of bronchodilator therapy is recommended to improve lung function by enhancing mucociliary action.[52–53]

TABLE 37-2 Cystic Fibrosis Foundation Nutritional Assessment Parameters and Recommendations

- Age-appropriate BMI method should be utilized to assess weight and height.
- Better FEV_1 status at about 80% predicted or above was associated with BMI % at 50th percentile or higher.
- For children and adolescents aged 2 to 20 years, the CF Foundation recommends that weight-for-stature assessment use the BMI percentile method and that children and adolescents maintain a BMI at or above the 50th percentile.
- For children diagnosed before age 2 years, the CF Foundation recommends that children reach a weight-for-length status of 50th percentile by age 2 years.
- For adults aged 20 years and older, the CF Foundation recommends that weight-for-stature assessment use the BMI method and that women maintain a BMI ≥22, and men maintain a BMI ≥23.
- For adults aged 20 years and older, the CF Foundation recommends that unintentional weight loss be avoided. When encountered in patient care, unintentional weight loss should be evaluated in the context of the patient's usual weight and health status.

Inhaled hypertonic saline is a novel agent used for the treatment of CF. Hypertonic saline is recommended for patients ≥6 years of age. A study conducted in Australia showed that CF patients who surfed had better pulmonary outcomes than patients who did not surf.[54-55] Researchers believed that the inhalation of ocean water helped to improve FEV_1 in CF patients that surfed. In this study, 24 patients were randomly assigned to receive a daily treatment of 7% hypertonic saline with or without pretreatment of a control. Clearance and pulmonary function were measured during a 14-day period. Results showed significant improvement in FEV_1 and forced vital capacity (FVC), as well as improvement of respiratory symptoms in hypertonic saline patients. The study also demonstrated these patients were able to sustain mucus clearance for >8 hours. Other studies assessing the use of hypertonic saline have supported this study, showing an improvement in lung function and a 56% reduction in exacerbations.[52–56]

Dornase alfa (Pulmozyme®) is also recommended in all patients ≥6 years of age and is strongly recommended for patients with moderate to severe lung disease to improve lung function and reduce exacerbations. Three randomized controlled trials and a crossover trial involving 520 patients were conducted. Study results showed improvement in FEV_1 by 3.2% and a reduction in exacerbations.[52,57–58]

TABLE 37-3 Pancreatic Enzyme Supplements

Trade Name	Manufacturer	Lipase Units	Protease Units	Amylase Units	Dosage form	FDA Approval
Creon® 6	Solvay Pharmaceuticals, Inc.	6,000	19,000	30,000	Delayed Release Capsule, enteric coated microspheres	Approved

ANTIINFLAMMATORY THERAPIES

Pulmonary inflammation begins early in life, as shown by the predominance of proinflammatory mediators that can be seen on bronchiolar lavage. A normal inflammatory response to bacteria becomes pathologic in CF patients who have both a prolonged and exaggerated reaction. Treatment of this inflammatory response is crucial to treating the CF patient.

Antiinflammatory therapies must address the neutrophil response and inhaled therapies will target the endobronchial location, which is the site of inflammation. Using medications that terminate the inflammatory process may be effective. Airway clearance and antibiotics will help control the inflammatory stimulation. Steroids and nonsteroidal antiinflammatory drugs (NSAIDs) are not widely used due to long-term safety concerns. High-dose ibuprofen (20 to 30 mg per kilogram of body weight twice daily) has proven efficacious in a study where patients showed less decline in pulmonary function when compared to patients given placebo. Patients on high-dose ibuprofen were able to maintain weight and had less hospital admissions. The benefits of this regimen exceed the risks of GI complications and nephrotoxicity. Despite these outcomes, less than 10% of CF patients in the United States are on this regimen. The low number of patients utilizing this proven therapy may be related to the requirement to obtain a specific therapeutic level of ibuprofen, which in turn requires frequent blood draws for pharmacokinetic monitoring.[52,59–62]

Studies with macrolides have shown an inhibition of the neutrophil migration and decrease in production of proinflammatory mediators. It is unclear at this point if the antiinflammatory effects of macrolides are a combination of antimicrobial and/or immunomodulator mechanisms of action. A study conducted in Japan first demonstrated the benefit of macrolides against *P. aeruginosa*. Four randomized controlled trials have since demonstrated this effect with azithromycin (250 to 500 mg) given 3 times weekly, which has led to increased nutritional status and decreased pulmonary infections. Other treatments are under investigation, but larger studies are needed before they become recommended therapies.[52,59,63–64]

TABLE 37-4 Airway Clearance Therapies

Airway Clearance Medication	Dose
Albuterol	Two puffs prior to therapy 2–4 times a day
HyperSal™ (hypertonic saline)	4 mL delivered via nebulizer 2–4 times a day
Pulmozyme® (dornase alfa)	2.5 mg delivered via nebulizer 1–2 times a day

INFECTIOUS DISEASE

4 Antibiotic therapy plays two integral roles in the treatment of CF patients: improving pulmonary function and preventing pulmonary failure. Oral, intravenous, and aerosolized antibiotic formulations are indicated and utilized for patients who experience acute pulmonary exacerbations, are chronically infected with *P. aeruginosa*, or require prevention of chronic *P. aeruginosa* infection. A major disadvantage of treatment in CF patients is that pathogens are not fully eradicated from the airways and will often develop resistance. Unfortunately, this limits antimicrobial selection and can contribute to deterioration of pulmonary function.

Early in life, patients will routinely be colonized with *S. aureus* and then later with *P. aeruginosa*.

Prophylaxis for *S. aureus* colonization is not recommended because in a 5- to 7-year study of cephalexin prophylaxis in young CF children, although the outcomes were favorable with respect to decreased *S. aureus* colonization, there was an increase in frequency of *P. aeruginosa* infections. Ultimately, this study showed no significant improvement in health outcomes.[65,66]

The finding of *P. aeruginosa* on sputum culture is a predictor of morbidity and mortality. There are relatively few antibiotics available for the treatment of *P. aeruginosa*. Antibiotics available include: extended-spectrum penicillins, select cephalosporins, select carbapenems, aztreonam, quinolones, colistimethate, and aminoglycosides. The only two mechanisms of action represented in this group are cell-wall destruction and inhibited cell-wall synthesis by ribosomal attachment. Standard practice is to combine

these two mechanisms for the best bactericidal results. It is not unusual for patients to have multiple organisms growing in their sputum. The clinician can review the quantitative sputum culture for both the organisms present and the amount or colony forming units grown. By targeting the organisms with the most numerous organisms present and reviewing the susceptibility panels, the clinician can choose the most appropriate regimen. After years of drug exposure, older CF patients will exhibit multidrug resistant *P. aeruginosa*. At this point, sputum cultures can be sent to specialized laboratories that will test combinations of antibiotics and report out any synergy results. Aerosolized antibiotics are directly deposited into the lung, providing concentrations that may overcome the standard measures of resistance.[67]

Other organisms that may be seen are *Alcaligenes*, *Stenotrophomonas*, *Mycobacteria*, *Aspergillus*, and *Burkholderia*. The importance of *Alcaligenes* as a pathogen is not well described. Originally only thought to have a prevalence of 2.7%, better lab testing and more studies have found infection rates closer to 8% in CF patients greater than 6 years old.[68–71] *Stenotrophomonas* is intrinsically multidrug resistant and pathogenic. A risk factor for acquiring this organism may be broad spectrum antibiotic use (carbapenems and cephalosporins).[72–73] Quite often this bacteria is misidentified and confirmatory testing may show *Burkholderia*. Prevalence in American CF patients is reported to be 8.4%; however, some centers report incidence to be as high as 25%.[74–76] Treatment choices are trimethoprim-sulfamethoxazole or doxycycline. *Mycobacteria* have been reported with more frequency in the last 10 years. Species include *M. tuberculosis*, nontuberculosis *M. chelonei, M. fortuitum,* and *M. avium-intracellulare* (MAI). The impact of *Mycobacteria* in the CF patient is unclear. Caseating granulomas have been found in some patients with clinical disease, while other patients with nontuberculosis mycobacterium have shown no adverse consequences.[77–80] *Aspergillus* species has a prevalence of 10% to 25% in American CF patients. During the TOBI trials, patients treated with aerosolized tobramycin appeared to be more at risk for colonization with *Aspergillus* than the placebo group. Although *Aspergillus* does not directly inhibit lung function, it may cause allergic bronchopulmonary aspergillosis, which is an immunologic mediated response to the presence of *Aspergillus* in the lungs.[81–82] *B. cepacia* is now known to be a bacterial species called *genomovars*. Currently, up to 9 species have been identified. This organism is commonly misidentified as *P. aeruginosa* or *Stenotrophomonas*.

The two typical antimicrobial choices to treat *B. cepacia* are ceftazidime and sulfamethoxazole-trimethoprim. It is important to recognize the transmission of *B. cepacia* from patient to patient has been shown and therefore proper infection control precautions should be taken. *B. cepacia* is usually transmitted via droplet route.[83–85]

Although CF patients are not more susceptible to respiratory viral infections, the outcome of such illnesses may be more severe. Decline in pulmonary function can be directly related to the number of annual viral infections. Newborns diagnosed with CF should receive respiratory syncytial virus (RSV) prevention with Synagis®, a monoclonal antibody, for the first 2 years of life. Synagis® is usually dosed at 15 mg/kg intramuscularly once a month during the RSV season. All CF patients who are 6 months of age or older should receive the annual influenza vaccine.[86–92]

Tobramycin (TOBI®) is recommended in all patients ≥6 years of age, and is strongly recommended for patients with moderate to severe lung disease and *Pseudomonas* present in sputum cultures. Aerosolized antibiotics deliver drugs locally to the lung while decreasing the risk of systemic side effects. In 1998, the FDA approved TOBI® for treating bacterial lung infections in patients with CF. Routine monitoring of serum aminoglycoside levels is unnecessary for patients with normal renal function using approved doses. It is recommended that CF patients use a preservative-free formulation of aerosolized antibiotics to prevent occurrence of bronchospasm.[93]

Gellar et al describe the pharmacokinetics of inhaled TOBI®, specifically looking at sputum concentrations in CF patients receiving three cycles of routine TOBI® (i.e., 28 days on, 28 days off), 300 mg twice a day. The study followed 258 patients for 24 weeks, and showed that approximately 95% of patients achieved sputum concentrations of >25 times the MIC of *Pseudomonas* isolates. This confirmed that inhaled TOBI® can be efficacious in helping prevent the progression of lung disease. At 25 times the MIC, tobramycin has a bactericidal effect.[94](See **Table 37–5**.)

PHARMACOKINETICS

2 CF patients are unique in respect to a larger volume of distribution and a faster rate of clearance. With a larger volume of distribution, patients may require larger antibiotic doses. Dosing intervals become shorter because drugs are eliminated faster. Critically ill patients may vary from their baseline function and require closer monitoring. However, as patients age, they tend to approach normal population parameters. Therapeutic drug monitoring and necessary dosage and regimen adjustments are critical to the successful treatment of CF patients.

Once daily dosing of aminoglycosides is preferred for ease of home care administration, and may actually work well in this setting. However, given the possibility of a shortened half-life, each patient's unique pharmacokinetic parameters must be calculated to determine if once daily dosing is appropriate.[95–97]

REPRODUCTION

Fertility discussions with older CF patients may arise during clinic visits, and these conversations should include genetic counseling and options for contraception. Drug-drug interactions between oral contraceptive pills (OCPs) and antibiotics should be monitored. Studies have shown that OCP use in CF patients is safe and effective in comparison with other contraception methods. Patches may not reliably adhere to the skin as a result of increased sweat on the surface of the skin.

The issues surrounding the use of contraception among CF men are similar to those among the normal population. CF men should not assume they are infertile and should adhere to using protective measures in order to prevent unwanted pregnancy and the spread of sexually transmitted diseases. Should a CF male with a nonfunctioning vas deferens desire to become a biological parent, microsurgical epididymal aspiration of spermatozoa with intracytoplasmic sperm injection into the oocyte can be performed.[16]

DIABETES

As CF patients live longer, glucose intolerance and CF-related diabetes (CFRD) are common complications. Even though it shares features of type 1 and type 2 diabetes, CFRD is unique because it is influenced by factors specific to CF, including: insulin deficiency, undernutrition, chronic and acute infection, elevated energy expenditure, glucagon deficiency, malabsorption, abnormal intestinal transit time, and liver dysfunction.[98] In comparison with the general CF population, patients with CFRD show a higher mortality rate. In a study of 448 patients, 60% of non-CFRD population and 25% of the CFRD population were alive at age 30. The average

TABLE 37-5 Anti-microbial agents utilized in CF

Antibiotic	Pediatric Dose (mg/kg/day)	Adult Dose	Frequency Range	Pathogens
Oral				
Ciprofloxacin	40	750 mg	Q 12 H	*Pseudomonas, Alcaligenes*
Sulfamethoxazole/Trimethoprim	15-20 mg of TMP	15-20 mg of TMP/kg/day	Q 6-8H	*Staphylococcus* (MRSA, MSSA),*Burkhoderia Stenotrophomonas, Alcaligenes*
Doxycycline	2-4	Max 200 mg/day	Q12-24H	*Stenotrophomonas, Staphylococcus*
Intravenous				
Amikacin	22.5-30	15 mg/kg/day	Q8H	*Pseudomonas*
Aztreonam	200	2 grams	Q6-8H	*Pseudomonas*
Cefepime	150	2 grams	Q8H	*Pseudomonas*
Ceftazidime	150	2 grams	Q8H	*Pseudomonas, Burkhoderia Alcaligenes*
Ciprofloxacin	30	400 mg	Q8H	*Pseudomonas, Alcaligenes*
Colistimethate	5-8	5-8 mg/kg/day	Q8H	*Pseudomonas*
Doxycycline	2-4	Max 200 mg/day	Q12-24H	*Stenotrophomonas, Staphylococcus*
Gentamicin	7.5-10	7.5-10 mg/kg/day	Q6-8H	*Pseudomonas*
Imipenem	60-100	2-4 grams	Q6H	*Pseudomonas, Burkhoderia Alcaligenes*
Meropenem	30-50	1-2 grams	Q8H	*Pseudomonas, Burkhoderia, Alcaligenes*
Piperacillin-Tazobactam	300-400 (piperacillin component)	4.5 grams	Q4-6H	*Pseudomonas, Alcaligenes, Staphylococcus* MSSA
Ticarcillin-Clavulanate	300-400 (ticarcillin component)	3.1 grams	Q4H	*Pseudomonas, Alcaligenes Staphylococcus* (MSSA)
Tobramycin	7.5-10	7.5-10 mg/kg/day	Q6-8H	*Pseudomonas*
Vancomycin	60	15 mg/kg	Q 6-12H	*Staphylococcus*(MRSA, MSSA)
Inhalation				
Tobramycin	60-600 mg/day	60-600 mg/day	Q12H	*Pseudomonas*
Colistimethate	75 mg/day	75 mg /day	Q12H	*Pseudomonas*
Aztreonam	225 mg/day	225 mg/day	Q8H	*Pseudomonas*

onset of CFRD is between 18 and 21 years, with a slight female predominance and is more commonly seen in CF gene mutation ΔF508.[98–102]

A desired goal in this population is to control hyperglycemia and hypoglycemia in order to reduce acute and chronic diabetes complications. Because insulin deficiency is the hallmark of CFRD, insulin is the recommended medical treatment. Insulin regimens are individualized based on the patient's lifestyle and circumstances. Exercise is encouraged because it can improve peripheral insulin sensitivity and have beneficial effects in overall health, pulmonary function, and well being.[99–102]

Oral antidiabetic agents have inconsistent results in literature, therefore, support for their use in therapy for CFRD patients is not recommended. Medications that help improve insulin sensitivity do not address the primary problem of insulin deficiency in CF. Metformin's mechanism of action is to improve hepatic and peripheral insulin sensitivity; however, it is contraindicated for patients with hypoxia due to the risk of fatal lactic acidosis. Additionally, metformin's multiple GI effects include anorexia, diarrhea, flatulence, and abdominal discomfort. Thiazolidinediones help to enhance peripheral insulin sensitivity, but there is serious potential for hepatic toxicity due to the underlying liver problems in CF patients. The use of acarbose is also discouraged due to its mechanism of action, which reduces postprandial glucose and insulin excursion by limiting intestinal absorption of glucose. This inhibits the energy absorption in malnourished individuals while causing diarrhea, anorexia, and abdominal discomfort. Sulfonylureas are being considered due to their ability to enhance insulin secretion by acting on a specific islet beta cell receptor, however, evidence has also shown that these agents bind and inhibit the CFTR. Use of sulfonylureas is not recommended at this time.[99,103]

SPECIAL POPULATIONS

PREGNANCY

As women with CF live longer, more choose to become pregnant. CF women considering pregnancy and their partners should both undergo genetic counseling. CF women who become pregnant are considered a high-risk pregnancy; therefore, several considerations should be addressed at the onset of and during pregnancy. At the beginning, both current medications and medications that might be used to treat exacerbations need to be considered. Several of these medications are classified as category C and may pose a potential harm to the fetus. These patients should also be screened and treated accordingly for CFRD.

Several complications that will arise during CF pregnancy include increases in minute ventilation, increased oxygen uptake, and increased blood volume and cardiac output. In a woman with severe lung disease, these changes can cause right-sided heart failure.

Other pharmacotherapy issues that are seen in this population are altered pharmacokinetics and increased maintenance of nutritional and pulmonary health.

The addition of the fetus impacts the CF woman's health by placing a strain on a precariously balanced state of being. The CF woman who chooses to breastfeed must take into account the additional nutritional requirement of approximately 500 kcal/day.[16]

PEDIATRICS

Education of the parents is emphasized in this population, concerning administration of pancreatic enzymes and infant

formula. Parents are also counseled to encourage their child to adhere with pulmonary health and nutritional health practices. As the child grows into adolescence, compliance becomes an issue. Peer pressure and social restraints may interfere with CF compliance and may influence the patients to disregard their personal well being.

TRANSPLANT PATIENTS

Lung transplantation has become an option with a 5-year survival rate of approximately 50%. Criteria for selection of transplant candidates include not only an FEV_1 of <30%, but also gender, nutritional status, diabetic status, sputum microbiology, and number of pulmonary exacerbations. Factors affecting compliance to CF care and to immunosuppressant therapy may also be taken under consideration for candidacy.[16]

NEW THERAPIES

Currently being studied are attempts to restore normal airway hydration, either by inhaled osmotic agents that bring water to the airway surface or by inhaled agents that may inhibit ion transport. One such agent is mannitol, which works by creating an osmotic gradient; this is being studied as a dried powder inhaler. Amiloride inhibits ion transport, but its short half-life limits its usefulness. Compounds with similar structures are also being studied for potential use.

Due to antibiotic resistance, new therapies for CF often focus on new antibiotics. Tobramycin inhaled powder (TIP) and inhaled aztreonam (AZLI) are both currently in phase 3 trials. TIP's advantage is that it is administered faster than TOBI®. AZLI uses a new nebulizer to also reduce treatment time. A new inhaled antibiotic, Arikace, is now in phase 2 trials. This liposomal amikacin penetrates into CF mucus and delivers high concentrations of the drug to the site of infection.[108,109] Cayston® (aztreonam powder) has recently received approval from the European commission. It will use the Altera® nebulizer, which will decrease administration time from 30 minutes to 3 minutes. This would significantly improve compliance and have a positive impact on quality of life in CF patients.[110]

CLINICAL CONTROVERSIES

CF is a worldwide problem, with a variety of approaches toward treatment. Discussions regarding controversial methods are constantly being held while new therapies are tried. Due to the relatively small population of CF patients, any studies that are conducted are frequently small in number or do not accurately reflect this population. This makes it difficult to extrapolate and come to a consensus regarding therapy. Some of these controversies will be discussed.

Inhaled and/or oral *N*-acetylcysteine (NAC) is an antioxidant that may have some antiinflammatory effect. The CF Foundation does not recommend this therapy due to insufficient evidence; however, a few published studies have led some clinicians to utilize this therapy. To date, there is not enough information to identify an NAC dosing strategy that is tolerable.[52,59,104]

Bisphosphonate therapy is being added to bone health regimens in both adult and pediatric patients. Pediatric CF trials with these medications have not been conducted, although adult CF trials indicated potential value. CF children will develop bone disease that forces clinicians to decide whether to utilize this controversial therapy. In adult CF patients, there have been a few studies assessing the use of injectable bisphosphonate. The use of intravenous pamidronate showed significant gains in bone mineral density (BMD), however there was a high incidence of adverse events, such as moderate-severe bone pain, fever, and phlebitis. Injectable formulations are useful to the CF population because they bypass the malabsorption issue. A once-a-week oral bisphosphonate trial is underway. There has been at least one promising adult study with oral alendronate; however, no study has been performed with risedronate.[42,49–50,105]

Colistimethate (Colistin®) is an antibiotic commonly used to treat pseudomonal infections. It is available in the injectable form that can be diluted and nebulized. Reports show a high incidence of bronchospasm and decline of FEV_1 in CF patients, especially in those with underlying reactive airway disease. Administration via inhalation can also be problematic due to low surface tension resulting in foaming of the solution. Thus, the recommended dose is questionable, due to variable drug delivery. However, for patients with multiple-drug-resistant pseudomonas, this may be the only alternative.[93,106–107]

SOCIAL

The social worker is an integral part of the CF team, due to the complex social issues that surround CF patients. Maintaining health insurance is a lifelong problem for CF patients. The inability to pay for CF meds may often influence compliance. Life insurance and homeowners insurance may never be obtainable. Maintaining employment is difficult because some employers may penalize for frequent hospitalizations. Thus, many CF patients have low paying jobs without insurance coverage.

Building relationships and confiding in others about personal health issues can be intimidating and difficult for CF patients. Children do not have opportunities to engage in friendships with other CF children. Due to infection control guidelines, group settings are limited. Support groups, although available, are restricted to online discussions. The decision to marry and have children is complicated by an awareness of a shortened life span.[16]

SUMMARY

Multidisciplinary care for CF patients should involve pulmonologists, gastroenterologists, pharmacists, social workers, respiratory therapists, and dieticians. Complexity of care requires good communication within the CF team. Although intravenous antibiotics have historically been a mainstay of therapy, recent focus has shifted to optimizing nutrition status and promoting effective pulmonary clearance. New treatment modalities such as inhaled antibiotics will necessitate greater involvement by pharmacists. As patients live longer, more issues that are social arise, and medical issues become more complex.

ABBREVIATIONS

ACT: airway clearance therapy

BMD: bone mineral density

BMI: body mass index

CF: cystic fibrosis
CFRD: cystic fibrosis-related diabetes
CFTR: cystic fibrosis transmembrane receptor
DIOS: distal intestinal obstruction syndrome
FDA: Food and Drug Administration
FEV_1: forced expiratory volume at 1 second
FVC: forced vital capacity
GI: gastrointestinal
IRT: immunoreactive trypsinogen
MIC: minimum inhibitory concentration
NAC: *N*-acetylcysteine
OGTT: oral glucose tolerance test
OCP: oral contraceptive pills
PEG: percutaneous endoscopic gastrostomy tube
PERT: pancreatic enzyme replacement therapy
QPIT: quantitative pilocarpine iontophoresis test
RSV: respiratory syncytial virus

SECTION 4
GASTROINTESTINAL DISORDERS

CHAPTER 38

Evaluation of the Gastrointestinal Tract

KEITH M. OLSEN AND GRANT F. HUTCHINS

KEY CONCEPTS

1. The patient history is key to evaluating gastrointestinal (GI) tract disorders and should include the problem onset, the setting in which it developed, and its presentation. Patient warning signs and alarm symptoms should be identified quickly and referral for further evaluation should be obtained in a prompt manner.
2. A complete physical examination should be performed, the severity and location of symptoms directing the focus of the examination.
3. Contrast agents barium sulfate and gastrografin allow evaluation of the hollow organs of the digestive tract for mucosally-based lesions as well as narrowing or strictures involving the GI tract.
4. The upper GI series involves radiographic visualization of the esophagus, stomach, and small intestine; whereas the lower GI series involves visualization of the colon and rectum.
5. Enteroclysis is used to evaluate the small bowel by introducing contrast agents by tube through the nose or mouth directly into the small intestine.
6. Trans-abdominal ultrasound, computed tomography, and magnetic resonance imaging provide images of the gallbladder, liver, pancreas, and abdominal wall.
7. Radionuclide imaging is sometimes useful to visualize and evaluate the liver, spleen, bile ducts, and gallbladder.
8. The endoscope, an illuminated optical instrument, remains the cornerstone of gastrointestinal diagnosis and most importantly therapy. Common examples of endoscopic procedures include esophagastroduodenoscopy, colonoscopy, enteroscopy, endoscopic retrograde cholangiopancreatography, and endoscopic ultrasound.
9. Capsule endoscopy, a newer less invasive endoscopic technique, takes pictures of the GI tract in the assessment of the small bowel in particular.
10. Ambulatory esophageal pH measurement is an important diagnostic test for gastroesophageal reflux disease and is often performed in conjunction with upper endoscopy. Most systems today are completely wireless and patient friendly.
11. Multichannel intraluminal impedance and pH monitoring combines acid exposure with impedance changes in resistant flow to aid the diagnosis of reflux in patients receiving a proton pump inhibitor and other antisecretory medications.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

The gastrointestinal (GI) tract is composed of organs and tissues that have diverse forms and functions. It includes the esophagus, stomach, small intestine, large intestine, colon, rectum, biliary tract, gallbladder, liver, and pancreas. Despite the rapid proliferation of technology for the diagnosis of digestive diseases, the patient history and physical examination remain important for initial assessment, triage, and direction of further diagnostic interventions. When combined with a thorough patient history and physical examination, diagnostic procedures are essential in the evaluation of GI disorders. This chapter describes the most commonly used clinical tools to evaluate patients with GI tract–related diseases.

SYMPTOMS OF GASTROINTESTINAL DYSFUNCTION

A variety of symptoms can arise from GI tract dysfunction, including heartburn, dyspepsia, abdominal pain, nausea, vomiting, diarrhea, constipation, and gastrointestinal bleeding. Signs and symptoms of malabsorption, hepatitis, and GI infection are also commonly seen. All clinicians must recognize warning symptoms that include weight loss, intractable vomiting, anemia, dysphagia, and bleeding; and a patient presenting with any of these symptoms should be immediately referred for further diagnostic interventions. The following sections describe methods that are commonly used to assess patients with GI complaints. For specific details concerning each GI disease state, please consult that particular chapter in this book.

PATIENT HISTORY

1 A comprehensive patient history is the cornerstone in the evaluation of a patient with digestive complaints. A clear, detailed, chronologic account of the patient's problems should be gathered. This account should include the onset of the problem, the setting in which it developed, factors that alleviate and aggravate the problem, and its manifestations. The symptom onset often provides important information that helps to formulate a differential diagnosis. For example, biliary colic or pain, such as that encountered with symptomatic gallstone disease, typically evolves over minutes and is present for hours, but pain caused by pancreatitis evolves over hours and lasts for days. The setting is always relevant as it provides clues to the possible origin of the disorder. For example, in the patient with complaints of reflux or ulcer disease, when do the symptoms occur? Are they alleviated or worsened by food and does the pain diminish when administered acid-suppressive therapy? Is the patient immunosuppressed (opportunistic infection vs diseases such as diabetes mellitus)? Also aiding in the diagnosis is the identification of factors that alleviate or exacerbate the principal symptom. For instance, ingesting a meal often relieves the pain of duodenal ulcer, but worsens that of gastric ulcer. The healthcare professional should ask questions that address potential etiologic possibilities, including motility disorders, structural diseases, malignancies, infections, psychosocial factors, dietary factors, and travel-associated diseases.[1,2] Questions concerning past medical and family history detailing illnesses, surgical interventions, injuries, foreign travel, living conditions, and habits are valuable (Table 38–1). A good cardiopulmonary history is also extremely relevant and should be performed during the overall history. A thorough medication use history is vital as many agents cause GI injury (Table 38–2).

TABLE 38-1 General Questions in a Gastrointestinal History

1. Tell me about the problem that you are experiencing. When did it start? What were you doing when the symptoms began?
2. Where is your pain located? Please point to the area where you feel pain. How rapidly did the pain come on? Is your pain constant or intermittent? What factors exacerbate or alleviate your pain? Does the pain awaken you at night?
3. Have you had these symptoms in the past?
4. What medications are you taking to help alleviate the pain? How much do you take? Do these medications work?
5. What other medications are you currently taking? Why are you taking them?
6. Have you recently had a change in dietary intake? If so, please describe. Can you draw any correlation between the foods that you eat and your gastrointestinal (GI) complaint?
7. Have you recently had a change in bowel habits? Have you experienced any diarrhea or constipation lately? Do you experience painful bowel movements?
8. Have you experienced any nausea or vomiting lately? If so, please describe conditions centered around this event.
9. Have you experienced any recent change in weight? Was this intentional? How many pounds have you gained or lost and over what time period did this occur? How has your appetite been?
10. Have you passed any blood from your rectum or vomited blood? Have you noticed any dark, tarry stools?
11. Have you had any acid indigestion?
12. Do you have difficulty swallowing?
13. Has anyone in your family experienced similar GI complaints? If so, please describe. Does anyone in your family have a history of GI disorders, including cancer of the GI tract?
14. Describe your past medical history, including illnesses and surgeries.
15. Please describe any past injuries that you have experienced.
16. Have you recently traveled outside of the United States? If so, where? When? How long did you stay? What kind of living conditions did you experience? What foods and drinks did you ingest?

TABLE 38-2 Drugs That May Cause Gastrointestinal Injury[15–17]

Gastrointestinal mucosal injury
Aspirin
Bisphosphonates
Chemotherapeutic agents
Corticosteroids
Ethacrynic acid
Ethanol
Iron preparations
Nonsteroidal antiinflammatory agents
Pancreatic enzymes
Potassium chloride
Reserpine
Warfarin
Jaundice
Acetohexamide
Androgens
Chlorpropamide
Corticosteroids
Erythromycin
Estrogens
Ethanol
Gold salts
Nitrofurantoin
Phenothiazines
Warfarin
Liver damage
Acetaminophen
Allopurinol
Amiodarone
Aminosalicylic acid
Dapsone
Erythromycin
Ethanol
Glyburide
Isoniazid
Ketoconazole
Lovastatin
Methotrexate
Methyldopa
Monoamine oxidase inhibitors
Nevirapine
Niacin
Nifedipine
Nitrofurantoin
Phenazopyridine
Phenytoin
Propylthiouracil
Rifampin
Salicylates
Sulfonamides
Telithromycin
Tetracycline
Valproic acid
Verapamil
Warfarin
Zidovudine
Pancreatitis
Azathioprine
Corticosteroids
Didanosine
Estrogens
Ethacrynic acid
Ethanol
Furosemide
Metronidazole
Opiates
Pentamidine
Sulfonamides
Tetracycline
Thiazides

PHYSICAL EXAMINATION

2 Many organ systems of the body interact and may provide important data needed for diagnosis, making it necessary to perform a thorough physical examination.[3] A comprehensive evaluation of the patient should be performed with notable attention to physical appearances and vital signs as they may suggest clues. A careful examination of the abdomen is an essential part of the gastrointestinal workup and classically includes inspection, auscultation, percussion, and palpation in this order. Inspection of the abdomen may reveal scars, hernias, bulges, or peristalsis. Auscultation is mainly focused on analysis of bowel sounds and identification of bruits and should be performed prior to percussion and/or palpation. Percussion of the abdomen allows for detection of tympany, measurement of visceral organ size, and detection of ascites. Palpation may allow the clinician to identify tenderness, rigidity, masses, and hernias. Moving from the abdominal exam, the digital rectal examination is used to detect rectal masses and tenderness, and to assess muscle tone. Stool on the examiner's glove obtained during rectal examination is often subjected to testing for detection of occult blood.[2,3] Patients presenting with upper gastrointestinal symptoms need more careful questioning to distinguish symptoms of reflux disease versus peptic ulcer disease. Additionally, once cardiovascular disease is eliminated, patients with chest pain may have a gastrointestinal source to their symptoms and further diagnostic workup may be needed.

LABORATORY AND MICROBIOLOGIC TESTS

Laboratory and microbiologic tests may be used to (a) assess organ function, (b) screen for certain GI disorders, and (c) evaluate the effectiveness of therapy. Laboratory testing should be viewed largely as supportive to an accurate history and physical examination. To achieve an accurate diagnosis and provide the best care, it is important to assess the patient's fluid and electrolyte status, nutritional status, and abdominal organ function. A complete blood cell count should be completed early in the evaluation to provide information concerning infection, malignancy, bone marrow suppression, anemia, and blood loss.[4] A serum chemistry panel provides clinicians with valuable information—involving several organ systems. For example, serum creatinine and blood urea nitrogen are often used as a measure of hydration status, as well as serving as indicators for renal function. Elevations in serum creatinine and blood urea nitrogen may be indicative of renal dysfunction or dehydration, and bleeding from the upper GI tract may lead to elevations in blood urea nitrogen. Albumin and prealbumin levels can be used to assess the patient's nutritional and hydration status and provide information concerning hepatic and renal function. Specifically, low albumin may be indicative of malnutrition, hepatic dysfunction, nephrotic syndromes, or protein-losing enteropathies. Serum measurements of sodium, chloride, and potassium are useful to determine electrolyte abnormalities associated with diarrheal illnesses.

More specific laboratory blood tests are often useful in classifying pancreaticobiliary disorders. Measurements of serum aspartate transaminase and alanine transaminase are elevated in most diseases of the liver, and serum alkaline phosphatase and bilirubin are often elevated in hepatobiliary disorders involving bile duct blockage. Prothrombin time and international normalized ratio are related to hepatocyte synthesis of vitamin K–dependent clotting factors and serve as indirect measurements of hepatic function. When evaluating patients with suspected pancreatitis, serum and urine measurements of amylase and lipase are important, because these will be elevated in many patients with acute pancreatitis (see Chapter 46).

Microbiologic and related studies are useful in evaluating patients with unexplained diarrhea, abdominal pain, and suspected GI infections. Stool may be examined to detect the presence of bacteria, parasites, or toxins. Pathogens most often responsible for infectious diarrhea and enteritis include bacteria such as *Shigella, Salmonella, Escherichia coli, Yersinia,* and *Clostridium difficile.* Viruses such as cytomegalovirus, especially in patients with acquired immune deficiency syndrome (AIDS), and parasites such as *Entamoeba histolytica* and *Giardia lamblia* are occasionally seen.[5] Patients presenting with watery diarrhea following antibiotic exposure within the previous 1 to 3 months should have their stool checked for *C difficile* toxins A and B. An additional organism *Helicobacter pylori* is a significant factor associated with peptic ulcer disease and MALT lymphomas; identification of this organism is critical in patients experiencing upper gastrointestinal symptoms and is often tested for during upper endoscopy (see Chapter 40).[5]

DIAGNOSIS

The patient's history, physical examination, and routine laboratory tests are valuable in establishing a diagnosis, but frequently more specific studies are required to confirm a clinical suspicion. The most appropriate diagnostic test depends on the anatomic region involved, the suspected abnormality, reliability of the test (e.g., sensitivity vs specificity), the patient's overall condition, and clinical manifestations of the patient. The next sections outline the most frequently used diagnostic studies and procedures and their roles in evaluating the GI tract.

RADIOLOGY

Radiologic procedures rely on the differential absorption of radiation of adjacent tissues to highlight anatomy and pathology. It is useful to divide radiologic testing into noncomputer- and computer-assisted procedures. Noncomputer-assisted radiologic procedures important in evaluating the GI tract include plain radiography, upper GI series with small bowel follow-through, lower GI series, and enteroclysis.[6,7]

Plain Radiography of the GI System

Radiographic evaluation of the GI tract often starts with plain films of the abdomen, which are noncontrast radiographs.[7] Specific abdominal structures that may be identified include the kidneys, ureters, and bladder. In addition, the esophagus, stomach, small and large intestine, and stones may be seen. Stones located within the gallbladder body and within the kidney are also sometimes seen on plain abdominal films. Plain films are often used to evaluate abdominal pain. Clinicians frequently employ plain radiographic fluoroscopy to guide and position other instruments that are used to evaluate and treat GI disorders; an example is the manipulation of dilation devices to treat esophageal strictures. Bowel obstruction and perforation are also sometimes seen using plain radiographic techniques, however the widespread availability of computed tomography (CT) scanning is gradually replacing these techniques.

Contrast Agents

3 Barium sulfate and/or gastrografin are the contrast agents of choice for studying the esophagus, stomach, and intestine.[7] Barium sulfate is a metallic material detected by radiography after swallowing the liquid agent; it is termed the *barium swallow.* Barium sulfate is not generally absorbed, and constipation is the most frequent adverse effect reported with its use. Barium sulfate and/or gastrografin can reveal mucosal defects and lumen size, and is helpful in diagnosing hiatal hernias, strictures along the GI tract, polyps, tumors, and in some cases ulcers. Upper endoscopy is largely replacing the contrast studies in the diagnosis of upper

GI tract disorders, but in certain instances can be a valuable tool in establishing a diagnosis prior to endoscopic evaluation. The barium esophagram should not serve as a primary diagnostic tool for patients with heartburn.

Upper GI Series

4 The upper GI series refers to the radiographic visualization of the esophagus, stomach, and small intestine. Patient preparation for an upper GI series usually consists of instructing patients to refrain from eating or drinking 8 to 12 hours prior to testing, which allows the upper GI tract to empty. A contrast agent such as barium sulfate or gastrografin is administered to the patient at the beginning of the study. The observed swallowing of the contrast agent permits visualization and monitoring of esophageal structural and motor functions. As the contrast medium flows into the stomach and small intestine, several regional radiographic films are taken to inspect these areas. This tracking of contrast agents through the small intestine is referred to as the *small bowel follow-through*. The upper GI series with small bowel follow-through commonly uncovers gastric cancer, peptic ulcer disease, esophagitis, gastric outlet obstruction, and can be suggestive of Crohn's disease (Fig. 38–1). In general, the barium swallow is plagued by low sensitivity and specificity for many GI disorders and as mentioned is being replaced by upper endoscopic techniques.

Lower GI Series

The lower GI series is used to examine the colon and rectum and is particularly useful if a colonic obstruction is suspected. Patients complaining of lower abdominal pain, constipation, or diarrhea are often referred for a lower GI series, also called a barium enema. The colon is prepared for the procedure by instructing the patient to refrain from eating or drinking 8 to 12 hours before the procedure, and by administering bowel-cleansing agents such as bisacodyl, magnesium citrate, magnesium hydroxide, or polyethylene glycol electrolyte (PEG) solution. During a lower GI series, a barium sulfate enema is given to contrast the terminal large intestine and rectum. The lower GI series is sometimes useful to detect and evaluate enterocolitis, obstructions, volvulus, and mucosal and structural lesions.[7]

FIGURE 38-1. Upper GI series with small bowel follow-through demonstrating narrowed distal terminal ileum and separation of small bowel loops (*arrow*). These findings are consistent with Crohn's disease.

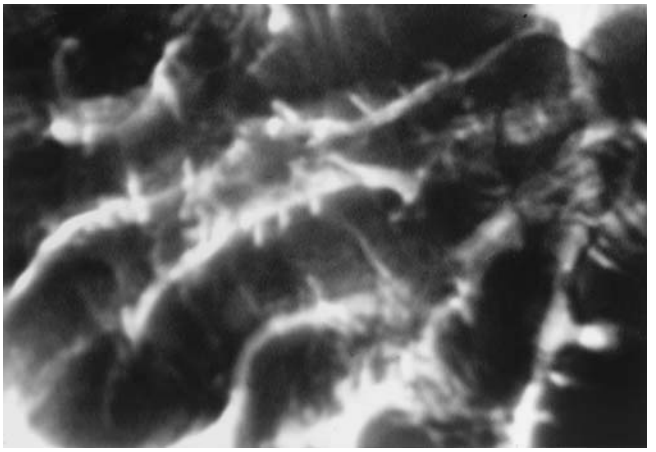

FIGURE 38-2. Normal small bowel enteroclysis. Contrast agents are instilled into the small bowel to highlight tumors, strictures, or other lesions. In this image, one can identify the normal circular folds.

Small Bowel Enteroclysis

5 Enteroclysis, or small bowel enema, refers to the technique of direct small bowel introduction of a contrast agent through a tube inserted through the patient's mouth or nose directly into the small intestine. Sequential radiographic films are taken of the small bowel as the contrast agent flows distally (Fig. 38–2). Because enteroclysis provides detailed imaging, it is an accurate method for evaluating the small bowel and for detecting small mucosal lesions that may be overlooked on the traditional small bowel follow-through.[9] Methylcellulose is used to enhance the detail of the small intestine in enteroclysis, thereby improving visualization. Patient preparation for this procedure involves instructing patients to refrain from eating or drinking 8 to 12 hours before testing and administering bowel-cleansing agents. The enteroclysis technique is a useful study for evaluation of the upper GI tract, but unfortunately it is not widely performed due to operator inexperience and is gradually being replaced by improved radiologic techniques such as CT or magnetic resonance imaging (MRI) enterography or more recently by small intestinal endoscopy known as single and double balloon enteroscopy.

IMAGING STUDIES

The second category of radiologic evaluation of the GI tract involves computer-assisted techniques, which allow a cross-sectional radiographic image of the body to be performed. Transabdominal ultrasonography, computed tomography, radionuclide scanning, and magnetic resonance imaging are frequently used imaging procedures for evaluating digestive disorders.[6,7]

Ultrasonography

6 Ultrasonography provides images of deeper structures such as the gallbladder, liver, and kidneys and can also be very useful in helping to define vascular abnormalities in the intra-abdominal

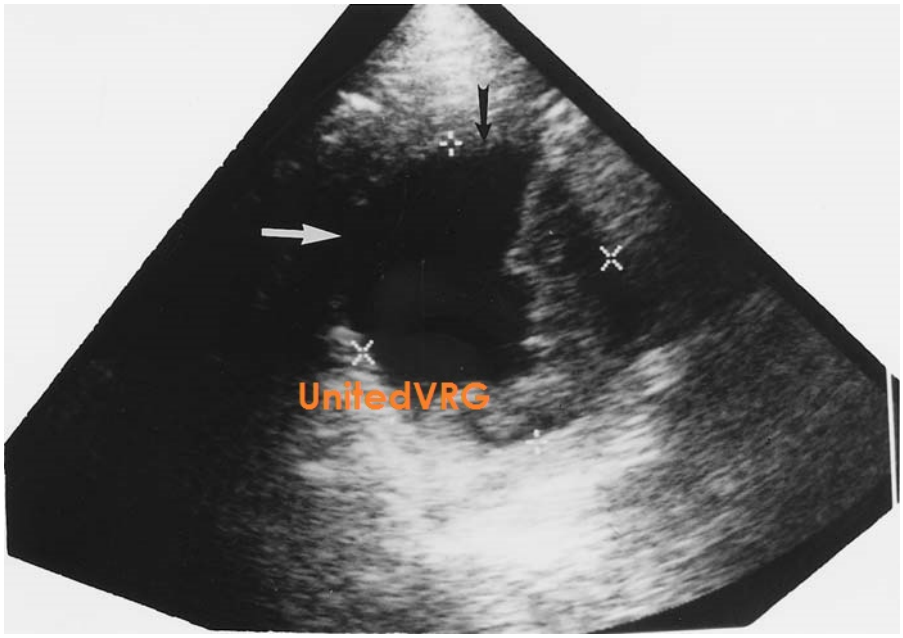

FIGURE 38-3. Abdominal ultrasonogram demonstrating a chronic pancreatic pseudocyst *(arrows)*.

cavity. Ultrasound involves the direction of a narrow beam of high-energy sound waves into the body and recording the reflections from the various organs and structures. Ultrasonography is noninvasive, relatively inexpensive, requires no ionizing radiation, and can be performed at bedside with a portable unit, and as such it is a well-accepted and useful technology. It accurately depicts gallstones presence within the gallbladder, helps define liver morphology, and is an excellent first test in the evaluation of the jaundiced patient to evaluate the absence or presence of biliary ductal dilation (Fig. 38–3). When combined with Doppler technologies, ultrasonography can image GI vascularity, in particular portal venous flow and in the early identification of aneurismal dilations of the abdominal aorta. Ultrasonography is limited by the presence of bowel gas and excessive amounts of body fat, particularly when evaluating deeper organs such as the pancreas.[6,7]

Computed Tomography

Computed tomography or computed axial tomography (CAT) scans provide detailed images of the GI system in which transverse planes of tissue are swept by a radiographic beam and a computer analysis of the variance in absorption produces a precise reconstructed image of that area.[6] Contrast agents may be added in a CT procedure to illuminate specific hollow structures and vascularity of the GI tract. The abdominal CT displays organs from the diaphragm down to the pelvic brim, and is especially valuable for detecting GI diseases of the liver, pancreas, spleen, and colon. Patient preparation for CT includes refraining from eating or drinking for a minimum of 4 hours before the test. The remarkable detail that CT offers in imaging organs and tissues adds to its popularity for evaluation of the GI system. CT scanning is rapidly replacing plane radiography of the abdomen due to its widespread availability, diminishing cost, and wealth of information gained. CT is useful in the identification of suspected intra-abdominal malignancy, pancreatitis, intra-abdominal abscesses, and cysts (Fig. 38–4).[6,7] Unlike ultrasonography, patient body size or the presence of gas does not limit the quality of imaging with CT. Contrast used during CT scanning is nephrotoxic and close attention to a patient's renal function is mandatory in these patients.

Radionuclide Imaging

❼ Radionuclide imaging involves intravenous injections of a radiopharmaceutical imaging agent and the use of a computerized detection camera to gather images. A secretory agent is sometimes given in addition to the radiopharmaceutical agent to improve sensitivity. Although the choice of a radiopharmaceutical agent depends on the specific organ or function being studied, the most commonly used agent is technetium (^{99m}Tc) tagged to a carrier molecule. Radionuclide imaging is sometimes useful to visualize the liver and spleen (liver-spleen scan), bile ducts, gallbladder (HIDA [hepatoimin-odiacetic acid] scan), and gut (tagged red blood cell).[6,7] Cysts, abscesses, tumors, and obstructions are detected and displayed as areas of differential uptake of radioactivity.[6] Radionuclide bleeding scans may detect hemorrhages and may assist in localization to help with therapeutic intervention. Contrast media nephrotoxicity in patients with preexisting renal impairment remains a clinically significant problem. Pretest treatment in high-risk patients with pharmacologic agents has demonstrated mixed results.

Magnetic Resonance Imaging

Magnetic resonance imaging and magnetic resonance cholangiopancreatography (MRCP) places the patient in close proximity to a high-strength magnetic field through which pulses of radiofrequency radiation are projected, thereby exciting the nuclei of hydrogen, phosphorus, oxygen, and other elements. The radiofrequency signals are manipulated and recorded by a computer, and a two-dimensional image representing a section of the patient is produced.[6,7] MRI has greater sensitivity for identifying liver tumors than do ultrasonography, CT, and radionuclide imaging. Significant advances in MRI technology and imaging capabilities often make this a preferred diagnostic test, particularly in the evaluation of pancreaticobiliary disorders.[6,7]

Arteriography

Arteriography of the gut depicts the configuration of visceral blood vessels after intravenous administration of a contrast medium. Arteriography may be employed for vascular anomalies such as an aneurismal dilation and in the evaluation of obscure bleeding

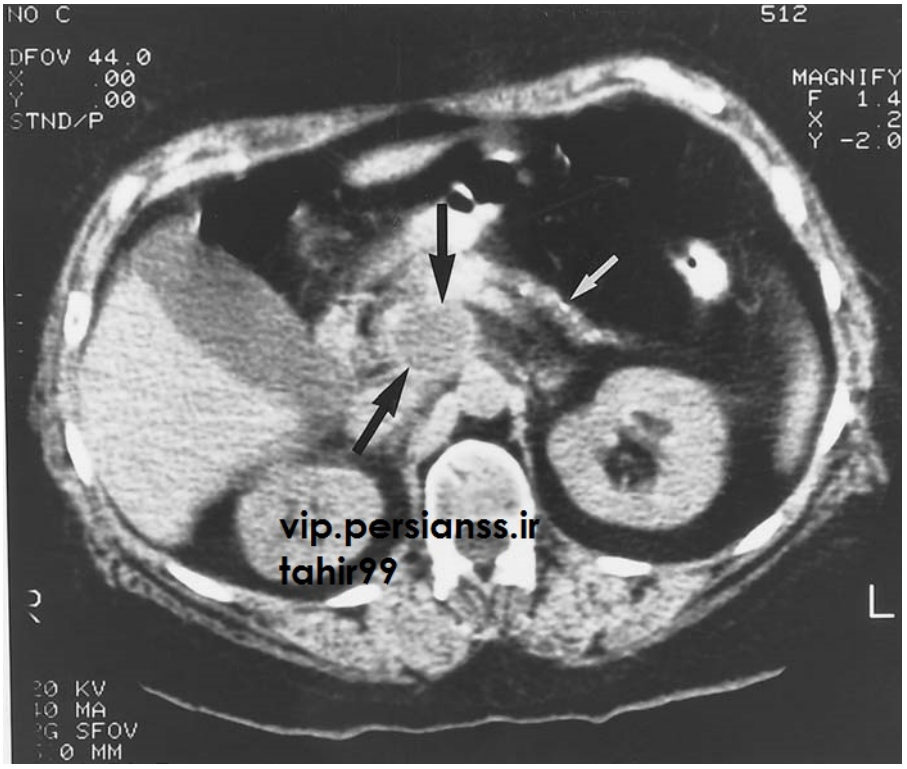

FIGURE 38-4. CT scan of the abdomen showing pancreatitis with calcification *(white arrow)* and pancreatic pseudocyst *(black arrows)*.

lesions. Therapeutic applications, including embolization of bleeding vessels, fistulas, and inoperable tumors.[6,7]

ENDOSCOPY

8 Refinement in optical engineering and fiber optics led to the development of the endoscope, which has revolutionized the management of GI disorders. Most endoscopic equipment today uses a computer chip device to provide high definition, detailed images of the particular lumen being examined. An endoscope is an illuminated white light and non-white light optical instrument designed to inspect the interior of the GI tract. Endoscopes enable the practitioner to inspect intraluminal mucosal lesions and to obtain biopsies and washings for cytology studies. Standard upper GI tract endoscopy (i.e., esophagogastroduodenoscopy [EGD]) is capable of inspecting the esophagus, stomach, and proximal small bowel. Lower GI tract endoscopic evaluation of the rectum and colon may be accomplished by colonoscopy or flexible-sigmoidoscopy. Standard upper and lower endoscopy can also be used to perform many therapeutic procedures and in addition many newer diagnostic and therapeutic endoscopic devices are now available.[8]

Preparation for endoscopic examinations includes instructing patients to refrain from eating or drinking for at least 8 to 12 hours prior to the endoscopic procedure. Bowel cleansing is necessary for colonoscopy and sigmoidoscopy using a variety of PEG-based solutions. Topical pharyngeal anesthetics, such as viscous lidocaine or benzocaine, usually improve patient acceptance of the upper endoscopic tube. Intravenous sedating agents, such as the benzodiazepines, lorazepam, midazolam, and, more recently, propofol, are among the most common agents used to induce differing levels of sedation, most commonly "conscious sedation" prior to the endoscopy. These sedating agents tend to improve patient acceptance and ease of the procedure. The agents should not be used without appropriate monitoring and the availability of flumazenil, a benzodiazepine antagonist. Serious adverse events have occurred with these agents when used for conscious sedation. In addition, antimuscarinic agents such as atropine sulfate are occasionally used for their cardiovascular effects, such as increasing a patient's heart rate, or for their antispasmodic effects, such as reducing duodenal and colonic motility. Because of its effectiveness at reducing bowel motility, glucagon may be used. Endoscopy should be pursued with caution in patients with severe respiratory or cardiac failure, and endoscopy is contraindicated for patients with suspected perforated viscera. The most commonly used endoscopic studies are upper endoscopy (EGD), colonoscopy, flexible sigmoidoscopy, and endoscopic retrograde cholangiopancreatography (ERCP).[8] Newer endoscopic techniques include capsule endoscopy, endoscopic ultrasound (EUS), and single or double balloon enteroscopy. These techniques are outlined in detail below.

Esophagogastroduodenoscopy is used to examine the esophagus, stomach, and duodenum. Patient preparation for EGD includes fasting for at least 6 to 8 hours prior to the procedure and the administration of sedatives and topical anesthetics. Common indications include evaluation of suspected upper GI bleeding, obstructions, upper abdominal pain, and persistent vomiting. Evaluation of radiographic abnormalities is also a frequent procedural indication.[12] EGD can be used therapeutically in upper gastrointestinal bleeding for ligation procedures involving esophageal varices, sclerosing or vasoconstrictive agent administration at the site of the bleed in peptic ulcer induced bleeding, or via the use of a thermal device such as a gold probe or heater probe on a bleeding vessel. In addition to its therapeutic potential, EGD commonly uncovers peptic ulcer disease and is the method of choice to diagnose Barrett's esophagus, a premalignant condition of the esophagus and other esophageal ulcer erosive disorders (Fig. 38–5). Once viewed as the method of choice to diagnosis gastroesophageal reflux disease, upper endoscopy, although commonly used, is often times not performed before a trial of a proton pump inhibitor has been undertaken. The favorable side-effect profile of proton pump inhibitors in addition to their superior healing ability make these agents extremely power-

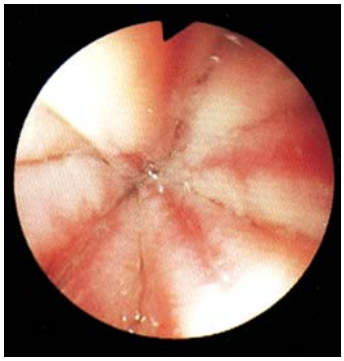

FIGURE 38-5. EGD demonstrating linear red streaks with a central white streak extended up the esophagus in peptic regurgitant esophagitis. *(From Kasper DL, Braunwald E, Hauser S, et al., eds. Harrison's Principles of Internal Medicine, 16th ed. New York: McGraw-Hill, 2005:1731, with permission.)*

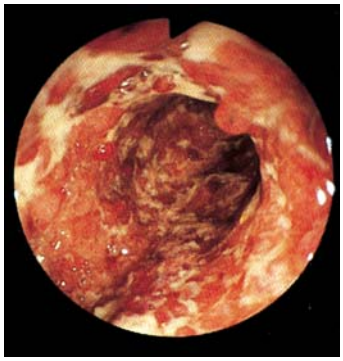

FIGURE 38-6. Sigmoidoscopic photograph demonstrating severe ulcerative colitis with diffuse ulceration, bleeding, and exudation. *(From Kasper DL, Braunwald E, Hauser S, et al., eds. Harrison's Principles of Internal Medicine, 16th ed. New York: McGraw-Hill, 2005:1732, with permission.)*

ful and widely prescribed by primary care physicians for heartburn and other symptoms attributed to gastroesophageal reflux disease. Primary care physicians usually refer patients for EGD only when they fail to respond to a course of proton pump inhibitor therapy, and by the time an endoscopy is performed the examination is likely to reveal normal-appearing mucosa. Even in patients undergoing upper endoscopy in the evaluation of reflux type symptomatology in the absence of proton pump inhibitor therapy, endoscopy will be normal in up to 50% of patients.[8]

Colonoscopy

Colonoscopy permits direct examination of the large intestine and rectum. To prepare for colonoscopy, the patient should fast for at least 8 to 12 hours prior to the examination, and bowel cleansing should be completed. Bowel preparations have traditionally involved a PEG-based or phosphate-based solution. However, because of concerns regarding phosphate-induced nephropathy, there has been a return to standard PEG-based solutions. A benzodiazepine and a short-acting narcotic agent are given to produce conscious sedation and in patients refractory or intolerant to conscious sedation agents, propofol is often administered to provide a deeper level of sedation. As with upper GI endoscopy, indications for lower GI endoscopy can be either diagnostic or therapeutic in nature. Common indications include evaluation and detection of abnormalities visualized by radiography, as well as diagnosis and therapy of GI hemorrhage, and importantly, screening patients for colorectal carcinoma. Additionally colonoscopy remains an invaluable procedure in the diagnosis, staging, and therapy of patients with inflammatory bowel disease (e.g., ulcerative colitis and Crohn's disease).[9]

Sigmoidoscopy

Flexible sigmoidoscopy is used to evaluate the sigmoid colon via the anorectum (Fig. 38–6). Flexible sigmoidoscopy has virtually replaced rigid sigmoidoscopy because of increased patient comfort and superior performance. The major indication for this examination is to evaluate symptoms related to the distal colon or rectum, such as hematochezia, painful defecation, and unexplained diarrhea. Flexible sigmoidoscopy is gradually being replaced by full colonoscopy in the evaluation and screening of patients for colorectal carcinoma. Patient preparation involves instructing patients to abstain from eating or drinking for at least 8 hours prior to the procedure and the administering of bowel-cleansing agents. Anoscopy is especially useful in evaluating the anus. The major indications for anoscopic examination include symptoms related to the anus and rectum, such as bleeding, protruding anorectal lesions, pain with defecation in particular, and severe itching. Patients undergoing sigmoidoscopy or anoscopy generally do not require sedation.

Endoscopic Retrograde Cholangiopancreatography

Endoscopic retrograde cholangiopancreatography is an important procedure that is used to evaluate and treat diseases of the pancreaticobilary tree. Common indications include common bile duct stone diagnosis and management, bile and pancreatic duct stricture management, and in the diagnosis and therapy of patients with biliary tract and/or pancreatic malignancies. Contrast injection following wire-guided bile or pancreatic duct cannulation reveals abnormalities such as obstruction due to malignancy or fluid collections, calculi, and strictures can be examined. ERCP also allows for the use of therapeutic techniques such as biliary or pancreatic sphincterotomy, removal of ductal stones from the common bile duct or main pancreatic duct, and in the stenting of biliary or pancreatic strictures. ERCP is also a useful method for tissue acquisition in the pancreaticobiliary tract using a variety of brush and biopsy devices. Recent advances in ERCP include the addition of direct bile duct or pancreatic duct visualization, a procedure which has greatly aided in the diagnosis and therapy of pancreaticobiliary disorders. Preparation for ERCP consists of conscious sedation and glucagon to relax gut motility and often requires the use of an anesthesiologist due to the complex and long procedural times associated with ERCP (Fig. 38–7).[7,9]

Endoscopic Ultrasound

Endoscopic ultrasound is a newer, exciting endoscopic technology which represents a marriage between upper endoscopy and standard ultrasound techniques. A high frequency ultrasound probe is attached to the working end of a diagnostic (radial array) or therapeutic (linear array) oblique viewing echoendoscope. Endoscopic ultrasound is commonly used to stage and diagnose upper GI tract malignancies such as those involving the esophagus, stomach, and pancreas. Upper GI tract locoregional tumor staging and tissue acquisition is highly sensitive and specific and provides a less invasive manner of tissue acquisition in many cases. Expanded uses of EUS include diagnosis and management of pancreatic fluid collections including pancreatic cystic neoplasms (non-pseudocystic), celiac plexus block vs neurolysis in pancreatic malignant and chronic pancreatitis patients, and in some centers in the direct instillation of antitumor agents into

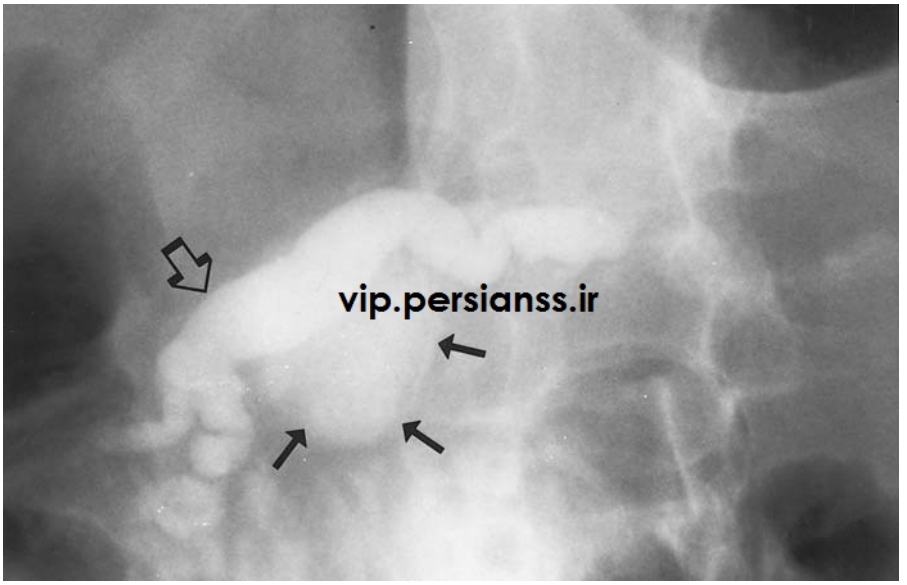

FIGURE 38-7. Endoscopic retrograde cholangiopancreatography (ERCP) demonstrating a dilated, irregular pancreatic duct with areas of stricturing *(large arrow)*. A pancreatic pseudocyst is visible immediately adjacent to the spine *(small arrows)*.

pancreatic malignancies. Lower GI tract EUS is also commonly performed most often in the diagnosis and locoregional staging of anorectal carcinoma and in evaluation of the anal sphincters. EUS is an invaluable tool in the management of GI tract disorders but does remain centered largely in academic, tertiary care referral institutions.

Enteroscopy

Enteroscopy, or direct visualization of the small intestine, has traditionally been limited to examination of the proximal most portions of the duodenum/jejunum because of excessive endoscope looping and discomfort to the patient during the examination. To overcome these difficulties two newer techniques, single and double balloon enteroscopy, have been developed. These particular enteroscopes involve sequential inflation and deflation of balloon attachment devices in order to sequentially "walk" the enteroscope down the small or large intestine. A combination of inflation, deflation, and endoscope reduction via torque and withdrawal allow for a pleating of the mucosal surface being examined. Complete traversal of the small intestine is routinely achieved via the oral route and significant traversal of the colon and distal small intestine is now possible from the rectal route. Common indications for these procedures include the evaluation of obscure GI bleeding, the diagnosis and evaluation of possible inflammatory bowel disease, and in the evaluation of radiologically discovered lesions such as mass or bowel wall thickening.

Capsule Endoscopy

9 Capsule endoscopy allows the visualization of the esophagus, stomach, and small intestine. This device consists of a vitamin pill–sized video camera that is swallowed and acts as an endoscope (Fig. 38–8). As the video capsule travels naturally through the digestive tract, images are transmitted to a recording device placed on the patient's hip. Patients return the recording device to the practitioner so that the images can be downloaded to a computer and evaluated. Eventually, the camera is naturally excreted and not retrieved.[10] Capsule endoscopy represents a noninvasive means to evaluate the upper and lower GI tracts but unfortunately lacks therapeutic capability. Capsule endoscopy is often used in the evaluation of obscure GI bleeding and in the evaluation of suspected inflammatory bowel disease and is often times used in conjunction with single or double balloon enteroscopy.

MISCELLANEOUS TESTS

Esophageal Manometry

Esophageal manometry is used to evaluate diseases of the esophagus by assessing esophageal motor functions. Common indications for this procedure include dysphagia and obscure chest pain. A special catheter equipped with pressure transducers is placed into the esophagus to measure esophageal pressures and peristalsis. Provocative testing with pharmacologic agents such as edrophonium chloride, a cholinergic muscle stimulant, may be used to precipitate esophageal pain during this procedure. Typical indications for esophageal manometry include evaluating suspected esophageal dysmotility, nonobstructive dysphagia, obscure chest pain, intestinal pseudo-obstruction, achalasia, and aiding in the positioning instruments such as pH probes. Esophageal manometry almost always is performed following endoscopic evaluation of the upper GI tract and can be a valuable tool in diagnosing many nonspecific disorders of the upper GI tract.

Ambulatory Esophageal pH Monitoring

10 Esophageal pH monitoring is considered by many clinicians as the gold standard in the evaluation of patients who complain

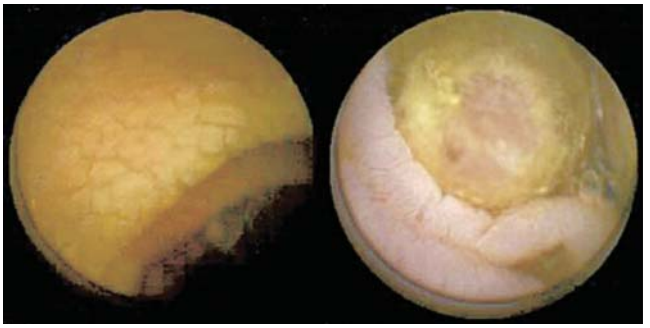

FIGURE 38-8. Capsule endoscopy images of a mildly scalloped jejuna fold (left) and an ileal tumor (right) in a patient with celiac sprue. *(From Kasper DL, Braunwald E, Hauser S, et al., eds. FIGURE 38-9. Ambulatory pH monitoring. The pH recordings from two esophageal probes are plotted over a 3-hour interval. Notice that the patient's symptom of regurgitation correlates with a low pH (<4) event *(arrow)*.

of gastroesophageal reflux. Ambulatory 24-hour pH monitoring is an elegant way to link esophageal acid exposure, as detected by a probe in the esophagus, with patient symptoms. The pH probe is placed approximately 5 cm above the distal esophagus. Because intraesophageal pH is normally higher (pH 6) than that of the stomach (pH approximately 1–3), the pH probe will record a decrease in pH if gastroesophageal reflux occurs. The most accepted method to identify gastroesophageal reflux during monitoring is the sudden decrease in pH below 4.0. The ambulatory 24-hour pH study links the patient's symptom to an acid event (Fig. 38–9). Wireless pH monitoring systems have gradually replaced the older methods that required a wire probe placement. A capsule is attached to the distal esophagus by a delivery system. The capsule then transmits measured pH data to a receiver by radiotelemetry technique. Wireless systems offer the advantage of better patient acceptance and extended monitoring of up to 96 hours versus 24 hours of the wire method. There are limitations to ambulatory pH monitoring in patients receiving proton pump inhibitor therapy or in the detection of nonacidic or weakly acidic refluxate.[11]

⓫ Multichannel intraluminal impedance monitoring is an emerging technique to study acid and nonacid reflux. The method combines pH measurements with manometry that enables the measurement of and distinction between swallowing and reflux. In patients whose symptoms have not responded to empiric proton pump inhibitor therapy in GERD, the test can separate those in whom symptoms are associated with acid reflux from those in whom symptoms are associated with nonacid reflux. Outcomes studies are required to further evaluate the usefulness of this diagnostic method; however, accumulating data are extremely promising.[12,13]

The Bernstein test, an older procedure that is used to measure gastric fluid pH, has largely been replaced by ambulatory pH monitoring. The procedure requires inserting a nasogastric tube and administrating alternating dripped solutions of normal saline and 0.1 N hydrochloric acid (HCl) into the esophagus via the nasogastric tube. If patient symptoms are reproduced by the acid perfusion and not the saline, the study is considered abnormal and indicative of acid hypersensitivity.[14]

Laparoscopy

Laparoscopy uses a tube-like device with an elaborate optical system that permits distinct visualization of the peritoneal cavity. General anesthesia is often required and a surgical incision is made in the abdomen to allow the passage of the laparoscope. The exterior of the liver, gallbladder, spleen, peritoneum, diaphragm, and pelvic organs may be examined during the laparoscopic examination. Similar to the other endoscopic techniques mentioned, biopsies and therapeutic interventions may be performed during the laparoscopy. Laparoscopy, it is important to remember, is extremely invasive. Reasons for doing laparoscopy include evaluating patients with abdominal masses, chronic abdominal pain of unclear etiology, abnormalities indicated on liver-spleen scan, such as acute or chronic cholecystitis, and to aid in the diagnosis and management of intra-abdominal malignancy.

CONCLUSIONS

Evaluation of the GI tract begins with a careful history and comprehensive physical examination. It then proceeds in a deliberate and thoughtful manner to establish the correct diagnosis and appropriate management of a given GI tract problem. Laboratory and microbiologic testing in addition to appropriate radiologic evaluation are often the initial steps in the evaluation of a patient with a particular GI tract complaint. GI tract endoscopy using a wide range of endoscopic devices with both diagnostic and therapeutic potential has entered the GI tract mainstream in recent years. Despite the wide array of testing and procedures available clinicians need to continue to perform a thorough history and physical examination and should be keenly aware of warning signs and symptoms that require immediate referral for further diagnostic studies and possible therapeutic intervention.

CHAPTER 39

Gastroesophageal Reflux Disease

DIANNE B. WILLIAMS AND ROBERT R. SCHADE

KEY CONCEPTS

1. Esophageal gastroesophageal reflux disease (GERD) syndromes can be described as symptom based or esophageal tissue injury based.
2. Endoscopy is used to evaluate mucosal damage from GERD and to assess for the presence of Barrett esophagus or other complications; ambulatory pH monitoring (with or without impedance monitoring) is useful for confirming GERD for patients with persistent symptoms without evidence of mucosal damage or for patients with atypical symptoms; manometry is useful for patients who are candidates for antireflux surgery and for ensuring proper placement of pH probes.
3. The goals of GERD treatment are to alleviate symptoms, decrease the frequency of recurrent disease, promote healing of mucosal injury, and prevent complications.
4. GERD treatment is determined by disease severity and includes lifestyle changes and patient-directed therapy, pharmacologic treatment, and antireflux surgery.
5. Patients with typical esophageal GERD syndromes should be treated with lifestyle modifications as appropriate and a trial of empiric acid-suppression therapy. Those who do not respond to empiric therapy or who present with alarm symptoms should undergo endoscopy.
6. Surgical intervention is a viable alternative treatment for select patients when long-term pharmacologic management is undesirable.
7. Acid suppression is the mainstay of GERD treatment. Proton pump inhibitors provide the greatest symptom relief and the highest healing rates, especially for patients with erosive disease or moderate to severe symptoms.
8. Many patients with GERD will relapse if treatment medication is withdrawn; so long-term maintenance treatment may be required. A proton pump inhibitor is the drug of choice for maintenance of patients with moderate to severe GERD.
9. Patient medication profiles should be reviewed for drugs that may aggravate GERD. Patients should be monitored for adverse drug reactions and potential drug–drug interactions.

The complete chapter, learning objectives, and other resources can be found at **www.pharmacotherapyonline.com**.

Gastroesophageal reflux disease (GERD) is a common medical disorder. A consensus definition of GERD states it is "a condition that occurs when the refluxed stomach contents lead to troublesome symptoms and/or complications."[1] The key is that these troublesome symptoms adversely affect the well-being of the patient. Episodic heartburn that is not frequent enough or painful enough to be considered bothersome by the patient is not included in this definition of GERD.[1]

Esophageal GERD syndromes are classified as either symptom-based or tissue injury based depending on how the patient presents.[1] Symptom-based esophageal GERD syndromes may exist with or without esophageal injury and most commonly present as heartburn, regurgitation or dysphagia. Less commonly, odynophagia (painful swallowing) or hypersalivation may occur. Tissue injury–based syndromes may exist with or without symptoms. The spectrum of injury includes esophagitis (inflammation of the lining of the esophagus), Barrett esophagus (when tissue lining the esophagus is replaced by tissue similar to the lining of the intestine), strictures, and esophageal adenocarcinoma.[2] Esophagitis occurs when the esophagus is repeatedly exposed to refluxed gastric contents for prolonged periods of time. This can progress to erosion of the squamous epithelium of the esophagus (erosive esophagitis). Complications of long-term reflux may include the development of strictures, Barrett esophagus, or possibly adenocarcinoma of the esophagus.

Gastroesophageal reflux symptoms associated with disease processes in organs other than the esophagus are referred to as *extraesophageal reflux syndromes*. Patients with extraesophageal reflux syndromes may present with reflux chest pain syndrome, laryngitis, or asthma. An association between these syndromes and GERD should only be considered when they occur along with esophageal GERD syndrome because these extraesophageal symptoms are nonspecific and have many other causes.[1]

Inflammation of the esophagitis (reflux esophagitis) can sometimes progress to erosions of the squamous epithelium of the esophagus; this is known as *erosive esophagitis*. Many patients suffering from mild GERD do not go on to develop erosive esophagitis and are often managed with lifestyle changes, antacids, and nonprescription histamine-2 (H_2) receptor antagonists or nonprescription proton pump inhibitors. Those with more severe symptoms (with or without tissue injury) predictably follow a course of relapsing disease, requiring more intensive treatment with acid-suppression therapy followed by long-term maintenance therapy. Antireflux surgery offers an alternative for select patients in whom prolonged medical management is undesirable.

EPIDEMIOLOGY

Gastroesophageal reflux disease occurs in people of all ages but is most common in those older than age 40 years. Although mortality associated with GERD is rare, GERD symptoms may have a significant impact on quality of life. The true prevalence and incidence of GERD is difficult to assess because many patients do not seek medical treatment, symptoms do not always correlate well with the severity of the disease, and there is no standardized definition or universal gold standard method for diagnosing the disease. However, 10% to 20% of adults in Western countries suffer from GERD symptoms on a weekly basis.[3]

The prevalence of GERD varies depending on the geographic region but appears highest in Western countries.[3] Except during pregnancy, there does not appear to be a major difference in incidence between men and women. Although gender does not generally play a major role in the development of GERD, it is an important factor in the development of Barrett esophagus. Barrett esophagus is most prevalent in white adult males in Western countries and may increase the risk for adenocarcinoma of the esophagus especially in white males. Alarmingly, adenocarcinoma of the esophagus has increased two- to sixfold over the past 2 decades.[2] The relationship of adenocarcinoma to Barrett esophagus, or even just long-standing GERD, which may be an independent risk factor for esophageal adenocarcinoma, is not clear.

Other risk factors and comorbidities that may contribute to the development or worsening of GERD symptoms include family history, obesity, smoking, alcohol consumption, certain medications and foods, respiratory diseases, and reflux chest pain syndrome.

PATHOPHYSIOLOGY

The key factor in the development of GERD is the abnormal reflux of gastric contents from the stomach into the esophagus.[4] In some cases, gastroesophageal reflux is associated with defective lower esophageal sphincter (LES) pressure or function. Patients may have decreased gastroesophageal sphincter pressures related to (a) spontaneous transient LES relaxations, (b) transient increases in intraabdominal pressure, or (c) an atonic LES, all of which may lead to the development of gastroesophageal reflux. Problems with other normal mucosal defense mechanisms, such as abnormal esophageal anatomy, improper esophageal clearance of gastric fluids, reduced mucosal resistance to acid, delayed or ineffective gastric emptying, inadequate production of epidermal growth factor, and reduced salivary buffering of acid, may also contribute to the development of GERD. Substances that may promote esophageal damage upon reflux into the esophagus include gastric acid, pepsin, bile acids, and pancreatic enzymes. Thus the composition and volume of the refluxate, as well as duration of exposure, are important aggressive factors in determining the consequences of gastroesophageal reflux. Rational therapeutic regimens in the treatment of gastroesophageal reflux are designed to maximize normal mucosal defense mechanisms and attenuate the aggressive factors.

LOWER ESOPHAGEAL SPHINCTER PRESSURE

The lower esophageal sphincter is a manometrically defined zone at the distal esophagus with an elevated basal resting pressure. The sphincter is normally in a tonic, contracted state, preventing the reflux of gastric material from the stomach but relaxes on swallowing to permit the free passage of food into the stomach. Mechanisms by which defective LES pressure may cause gastroesophageal reflux are threefold. First, and probably most importantly, reflux may occur following spontaneous transient LES relaxations that are not associated with swallowing. Although the exact mechanism is unknown, esophageal distension, vomiting, belching, and retching cause relaxation of the LES. While not thought to contribute significantly to erosive esophagitis, these transient relaxations, which are normal postprandially, may play an important role in symptom-based esophageal reflux syndromes. Transient decreases in sphincter pressure are responsible for more than half of the reflux episodes in patients with GERD. The propensity to develop gastroesophageal reflux secondary to transient decreases in LES pressure is probably dependent on numerous factors, including the degree of sphincter relaxation, efficacy of esophageal clearance, patient position (more common in recumbent position), gastric volume, and intragastric pressure. Second, reflux may occur following transient increases in intraabdominal pressure (stress reflux). An increase in intraabdominal pressure such as that occurring during straining, bending over, coughing, eating, or a Valsalva maneuver may overcome a weak LES, and thus may lead to reflux. Third, the LES may be atonic, thus permitting free reflux as seen in patients with scleroderma. Although transient relaxations are more likely to occur when there is normal LES pressure, the latter two mechanisms are more likely to occur when the LES pressure is decreased by such factors as fatty foods, gastric distension, smoking, or certain medications (Table 39–1).[5] Various foods aggravate esophageal reflux by decreasing LES pressure or by precipitating symptomatic reflux by direct mucosal irritation (e.g., spicy foods, orange juice, tomato juice, and coffee). Pregnancy is a condition in which reflux is common. There are many postulated reasons for the increased incidence of heartburn during pregnancy, including hormonal effects on esophageal muscle, LES tone, and physical factors (increased intraabdominal pressure) resulting from an enlarging uterus. A decrease in LES pressure resulting from any of the previously mentioned causes is not always associated with gastroesophageal reflux. Likewise, individuals who experience decreases in sphincter pressures and subsequently reflux, do not always develop GERD. The other natural defense mechanisms (anatomic factors, esophageal clearance,

TABLE 39-1 Foods and Medications That May Worsen GERD Symptoms

Foods	Medications
Decreased lower-esophageal sphincter pressure	
Fatty meal	Anticholinergics
Carminatives (peppermint, spearmint)	Barbituates
Chocolate	Caffeine
Coffee, cola, tea	Dihydropyridine calcium channel blockers
Garlic	Dopamine
Onions	Estrogen
Chili peppers	Ethanol
	Nicotine
	Nitrates
	Progesterone
	Tetracycline
	Theophylline
Direct irritants to the esophageal mucosa	
Spicy foods	Alendronate
Orange juice	Aspirin
Tomato juice	Nonsteroidal antiinflammatory drugs
Coffee	Iron
	Quinidine
	Potassium chloride

mucosal resistance, and other gastric factors) must be evoked to explain this phenomenon.

ANATOMIC FACTORS

Disruption of the normal anatomic barriers by a hiatal hernia (when a portion of the stomach protrudes through the diaphragm into the chest) was once thought to be a primary etiology of gastroesophageal reflux and esophagitis. Now it appears that a more important factor related to the presence or absence of symptoms in patients with hiatal hernia is the LES pressure. Patients with hypotensive LES pressures and large hiatal hernias are more likely to experience gastroesophageal reflux following abrupt increases in intraabdominal pressure compared with patients with a hypotensive LES and no hiatal hernia. Although anatomic factors are still considered significant by some, the diagnosis of hiatal hernia is currently considered a separate entity with which gastroesophageal reflux may simultaneously occur.

ESOPHAGEAL CLEARANCE

In many patients with GERD, the problem is not that they produce too much acid but that the acid produced spends too much time in contact with the esophageal mucosa. This is not surprising, because the symptoms and/or severity of damage produced by gastroesophageal reflux are partially dependent on the duration of contact between the gastric contents and the esophageal mucosa. This contact time is, in turn, dependent on the rate at which the esophagus clears the noxious material, as well as the frequency of reflux. The esophagus is cleared by primary peristalsis in response to swallowing, or by secondary peristalsis in response to esophageal distension and gravitational effects. Swallowing contributes to esophageal clearance by increasing salivary flow. Saliva contains bicarbonate that buffers the residual gastric material on the surface of the esophagus. The production of saliva decreases with increasing age, making it more difficult to maintain a neutral intraesophageal pH. Therefore, esophageal damage caused by reflux occurs more often in the elderly and similarly for patients with Sjögren syndrome or xerostomia. Swallowing is also decreased during sleep, making nocturnal GERD a problem in many patients.

MUCOSAL RESISTANCE

Within the esophageal mucosa and submucosa there are mucus-secreting glands that may contribute to the protection of the esophagus. Bicarbonate moving from the blood to the lumen can neutralize acidic refluxate in the esophagus. When the mucosa is repeatedly exposed to the refluxate in GERD, or if there is a defect in the normal mucosal defenses, hydrogen ions diffuse into the mucosa, leading to the cellular acidification and necrosis that ultimately cause esophagitis. In theory, mucosal resistance may be related not only to esophageal mucus but also to tight epithelial junctions, epithelial cell turnover, nitrogen balance, mucosal blood flow, tissue prostaglandins, and the acid–base status of the tissue. Saliva is also rich in epidermal growth factor, stimulating cell renewal.

GASTRIC EMPTYING

Delayed gastric emptying can contribute to gastroesophageal reflux. An increase in gastric volume may increase both the frequency of reflux and the amount of gastric fluid available to be refluxed. Gastric volume is related to the volume of material ingested, rate of gastric secretion, rate of gastric emptying, and amount and frequency of duodenal reflux into the stomach. Factors that increase gastric volume and/or decrease gastric emptying, such as smoking and high-fat meals, are often associated with gastroesophageal reflux. This partially explains the prevalence of postprandial gastroesophageal reflux. Fatty foods may increase postprandial gastroesophageal reflux by increasing gastric volume, delaying the gastric emptying rate, and decreasing the LES pressure. Patients with gastroesophageal reflux, particularly infants, may have a defect in gastric antral motility. The delay in emptying may promote regurgitation of feedings, which might, in turn, contribute to two common complications of GERD in infants (e.g., failure to thrive and pulmonary aspiration).[6]

COMPOSITION OF REFLUXATE

The composition, pH, and volume of the refluxate are important aggressive factors in determining the consequences of gastroesophageal reflux. In animals, acid has two primary effects when it refluxes into the esophagus. First, if the pH of the refluxate is less than 2, esophagitis may develop secondary to protein denaturation. In addition, pepsinogen is activated to pepsin at this pH and may also cause esophagitis. Duodenogastric reflux esophagitis, or "alkaline esophagitis," refers to esophagitis induced by the reflux of bilious and pancreatic fluid. The term *alkaline esophagitis* may be a misnomer in that the refluxate may be either weakly alkaline or acidic in nature. An increase in gastric bile concentrations may be caused by duodenogastric reflux as a result of a generalized motility disorder, slower clearance of the refluxate, or after surgery.[7] Although bile acids have both a direct irritant effect on the esophageal mucosa and an indirect effect of increasing hydrogen ion permeability of the mucosa, symptoms are more often related to acid reflux than to bile reflux. Specifically, the percentage of time that the esophageal pH is <4 is greater for patients with severe disease as compared with those with mild disease. Esophageal pH monitoring in conjunction with 24-hour bile monitoring has shown a higher incidence of Barrett esophagus for patients who have both acid and alkaline reflux.[7] More study is needed to substantiate this finding. Nevertheless, the combination of acid, pepsin, and/or bile is a potent refluxate in producing esophageal damage.

COMPLICATIONS

Several complications may occur with gastroesophageal reflux, including esophagitis, esophageal strictures, Barrett esophagus, and esophageal adenocarcinoma. Strictures are common in the distal esophagus and are generally 1 to 2 cm in length. The use of nonsteroidal antiinflammatory drugs or aspirin is an additional risk factor that may contribute to the development or worsening of GERD complications.[3] Although GERD may lead to esophageal bleeding, the blood loss is usually chronic and low grade in nature, but anemia may occur. In some patients, the reparative process leads to the replacement of the squamous epithelial lining of the esophagus by specialized columnar-type epithelium (Barrett esophagus), which increases the incidence of esophageal strictures by as much as 30%. Additionally, the risk of esophageal adenocarcinoma may be higher for patients with Barrett esophagus as compared with the general population.[8]

The pathophysiology of gastroesophageal reflux is a complex cyclic process. It is difficult, if not impossible, to determine which occurs first: gastroesophageal reflux leading to defective peristalsis with delayed clearing or an incompetent LES pressure leading to gastroesophageal reflux. Understanding the factors associated with the development of GERD provides insight into the treatment modalities currently used to manage patients suffering from this disease.

CLINICAL PRESENTATION

1 GERD syndromes can be described as symptom-based or esophageal tissue injury-based. Patients may also present with more complicated "alarm" symptoms which necessitates further diagnostic evaluation to differentiate other diseases as the cause. The spectrum of esophageal injury-based GERD syndromes includes esophagitis, strictures, Barrett esophagus and adenocarcinoma. The severity of the symptoms of gastroesophageal reflux does not always correlate with the degree of esophageal tissue injury, but it does correlate with the duration of reflux. Patients with symptom-based esophageal syndromes may have symptoms as severe as those with esophageal tissue injury. Patients may also present with extraesophageal syndromes that include atypical symptoms such as reflux chest pain syndrome, laryngitis, or asthma. It is important to distinguish GERD symptoms from those of other diseases, especially when chest pain or pulmonary symptoms are present. Interestingly, close to half of patients presenting with chest pain who have a normal electrocardiogram have GERD[9] and approximately half of patients with asthma have GERD.

The most useful tool in the diagnosis of gastroesophageal reflux is the clinical history, including presenting symptoms and associated risk factors. Patients presenting with typical symptoms of reflux do not usually require invasive esophageal evaluation. These patients generally benefit from an initial empiric trial of acid-suppression therapy. A clinical diagnosis of GERD can be assumed in patients who respond to appropriate therapy.[4] Further diagnostic evaluation is useful to prevent misdiagnosis, identify complications, and assess treatment failures.[2] Diagnostic tests should be performed in those patients who do not respond to therapy and for those who present with alarm symptoms (e.g., dysphagia, odynophagia, weight loss), which may be more indicative of more complicated disease.

2 Useful tests in diagnosing GERD include endoscopy, ambulatory pH or impedance monitoring, and manometry. A camera-containing capsule swallowed by the patient offers the newest technology for visualizing the esophageal mucosa via endoscopy. The PillCam ESO is less invasive than traditional endoscopy and takes less than 15 minutes to perform in the clinician's office. Images of the esophagus are downloaded through sensors placed on the patient's chest that are connected to a data collector. The camera-containing capsule is later eliminated in the stool. Endoscopy is not useful as a screening tool for Barrett esophagus and esophageal adenocarcinoma for patients with long-standing GERD.[1] Unfortunately, the presence or absence of mucosal damage does not prove the patient's symptoms are reflux related; for that, ambulatory pH monitoring is useful. Ambulatory pH monitoring can be performed by passing a small pH probe transnasally and placing it approximately 5 cm above the LES.[10,11] Patients are asked to keep a diary of symptoms that later are correlated with the pH measurement corresponding to the time the symptom was reported.

Two recent developments related to ambulatory reflux monitoring include (1) the use of combined *impedance–pH monitoring* and (2) the use a wireless method of pH monitoring.[4] Whereas ambulatory pH monitoring only measures acid reflux, combined impedance–pH monitoring measures both acid and nonacid reflux. The wireless pH-monitoring involves attaching a radiotelemetry capsule to the esophageal mucosa. The advantages of this method are that a longer period of monitoring is possible (48 hours), it may demonstrate superior recording accuracy compared with some catheter designs, and it is more comfortable for the patient because a nasogastric tube is unnecessary.[1] Proton pump inhibitor therapy should be withheld for 7 days prior to performing ambulatory catheter pH, impendance–pH, or wireless pH monitoring when evaluating patients who have failed an initial empiric therapy and who have normal findings on endoscopy and manometry.[1]

CLINICAL CONTROVERSY

Professional organizations differ in their recommendation for or against endoscopy as a screening tool for patients with chronic symptoms of GERD for the purpose of detecting Barrett esophagus and thereby reducing the risk of esophageal adenocarcinoma.

CLINICAL PRESENTATION OF GERD

Symptom-based esophageal GERD syndromes (with or without esophageal tissue injury)

Typical symptoms (May be aggravated by activities that worsen gastroesophageal reflux such as recumbent position, bending over, or eating a meal high in fat.)

- Heartburn (hallmark symptom described as a substernal sensation of warmth or burning rising up from the abdomen that may radiate to the neck. May be waxing and waning in character.
- Water brash (hypersalivation)
- Belching
- Regurgitation

Alarm symptoms (These symptoms may be indicative of complications of GERD such as Barrett esophagus, esophageal strictures, or esophageal adenocarcinoma.)

- Dysphagia
- Odynophagia

Tissue injury–based esophageal GERD syndromes (with or without esophageal symptoms)

Symptoms (May present with alarm symptoms such as dysphagia, odynophagia or unexplained weight loss.)

- Esophagitis
- Strictures
- Barrett esophagus
- Esophageal adenocarcinoma

Extraesophageal GERD syndromes

Symptoms (These symptoms have an association with GERD, but causality should only be considered if a concomitant esophageal GERD syndrome is also present.)

- Chronic cough
- Laryngitis
- Asthma
- Dental enamel erosion

Diagnostic tests for GERD

Clinical history

- Generally sufficient to clinically diagnose GERD for patients with typical symptoms.

Endoscopy

- Preferred for assessing the mucosa for esophagitis, identifying Barrett esophagus and diagnosing complications.
- Non-inflammatory GERD and major motor disorders may be missed by endoscopy.

- If no erosions, does not definitively show symptoms are GERD-related.

Ambulatory pH monitoring

- Identifies patients with excessive esophageal acid exposure and helps determine if symptoms are acid related.
- Useful for patients not responding to acid-suppression therapy.
- Documents the percentage of time the intraesophageal pH is <4 and determines the frequency and severity of reflux.
- Measures only acid reflux (not nonacid reflux).

Combined impedance–pH monitoring

- Measures both acid and nonacid reflux.

Manometry

- Ensure proper placement of esophageal pH probes (The recent advancement of the tubeless pH monitoring system using endoscopic landmarks for placement may negate the need for manometry for ensuring proper placement of esophageal pH probes.)
- Evaluate esophageal peristalsis and motility prior to antireflux surgery

Empiric trial of a proton pump inhibitor as a diagnostic test for GERD

- Less expensive and more convenient than ambulatory pH monitoring but lack standardized dosing regimen and duration of the diagnostic trial.

Barium radiography

- Not routinely used to diagnose GERD because lacks sensitivity and specificity; cannot identify Barrett esophagus.

Data from reference 2.

TREATMENT

Therapeutic modalities used in the treatment of gastroesophageal reflux are targeted at reversing the various pathophysiologic abnormalities.

DESIRED OUTCOMES

3 The goals of treatment are to (1) alleviate or eliminate the patient's symptoms, (2) decrease the frequency or recurrence and duration of gastroesophageal reflux, (3) promote healing of the injured mucosa, and (4) prevent the development of complications. Therapy is directed at augmenting defense mechanisms that prevent reflux and/or decrease the aggressive factors that worsen reflux or mucosal damage (Fig. 39–1). Therapy is directed at (1) decreasing the acidity of the refluxate, (2) decreasing the gastric volume available to be refluxed, (3) improving gastric emptying, (4) increasing LES pressure, (5) enhancing esophageal acid clearance, and (6) protecting the esophageal mucosa.

GENERAL APPROACH TO TREATMENT

4 The treatment of GERD is categorized into one of the following modalities: (1) lifestyle modifications and patient-directed therapy with antacids, nonprescription H_2-receptor antagonists, and/or nonprescription proton pump inhibitors; (2) pharmacologic intervention with prescription-strength acid-suppression therapy; (3) and antireflux surgery (Table 39–2). The initial therapeutic modality used is in part dependent on the patient's condition (frequency of symptoms, degree of esophagitis, and presence of complications) (Table 39–3). Historically, a step-up approach was used, starting with noninvasive lifestyle modifications and patient-directed therapy and progressing to pharmacologic management or antireflux surgery. A step-down approach, starting with a proton pump inhibitor given once or twice daily instead of an H_2-receptor antagonist and then stepping down to the lowest dose of acid suppression (either an H_2-receptor antagonist or proton pump inhibitor) needed to control symptoms, is also effective. Neither the step-up nor the step-down approach has superior efficacy over the other. The clinician should determine the most appropriate approach for the individual patient. Every attempt should be made to aggressively control symptoms and to prevent relapses early in the course of the patient's disease in order to prevent the complications. For patients with moderate to severe GERD, especially those with erosive disease, starting with a proton pump inhibitor as initial therapy is advocated because of its superior efficacy over H_2-receptor antagonists.

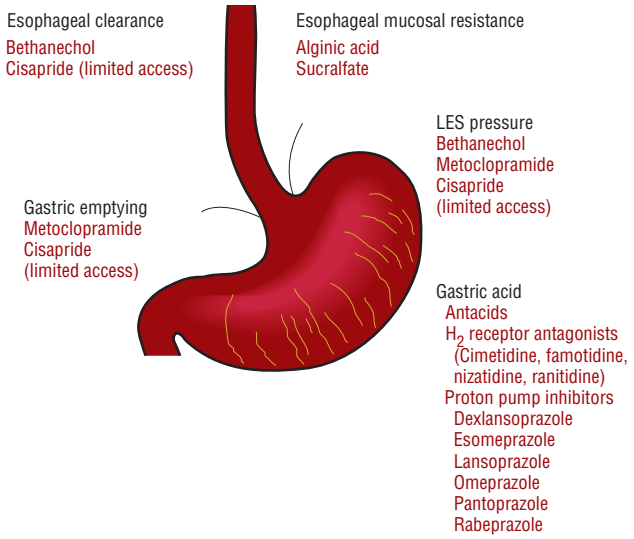

FIGURE 39-1. Therapeutic interventions in the management of gastroesophageal reflux disease. Pharmacologic interventions are targeted at improving defense mechanisms or decreasing aggressive factors (LES, lower esophageal sphincter).

While weight loss in obese patients and elevation of the head of the bed have proven beneficial for most GERD patients, recommending all lifestyle modifications to all patients is not recommended.[1] Instead, education on lifestyle modifications should be tailored to the individual needs of the patient. Table 39–4 lists many of the lifestyle modifications that can be recommended.[4]

5 Patients who do not respond to lifestyle modifications and patient-directed therapy after 2 weeks should seek medical attention and are generally started on empiric therapy consisting of an acid-suppression agent. Acid-suppression therapy with proton pump inhibitors or H_2-receptor antagonists is the mainstay of GERD treatment. Patients presenting with moderate to severe symptoms (with or without esophageal erosions) should be started on a proton pump inhibitor as initial therapy because it provides the most rapid symptomatic relief and healing in the highest percentage of patients.[4] H_2-Receptor antagonists in divided doses are effective for patients with milder GERD symptoms. Standard H_2-receptor antagonist doses may be increased to 2 to 4 times the normal dose for patients who do not respond to standard doses. However, if this is necessary, it is more cost-effective and efficacious to switch to a proton pump inhibitor.

TABLE 39-2 Evidence-Based Treatment Recommendations for GERD

Recommendations	Level of Evidence[a]
Lifestyle modifications	
Patients may benefit from lifestyle modifications but most will require acid-suppression therapy to control symptoms.	IV
Patient-directed therapy	
Nonprescription antacids, H_2-receptor antagonists, and proton pump inhibitors may be used for patients with mild, infrequent heartburn or regurgitation. Patients experiencing continuous symptoms for longer than 2 weeks should be seen by their clinician. Patients experiencing alarm symptoms should seek medical attention as soon as possible.	IV
Acid-suppression therapy	
Acid-suppression therapy is the preferred treatment for GERD. Proton pump inhibitors provide more rapid relief of symptoms and are more effective at healing the esophageal mucosa compared to H_2-receptor antagonists in patients with moderate to severe GERD.	I
Promotility therapy	
Promotility therapy may be useful in some patients when combined with acid-suppression therapy. They are generally not recommended as monotherapy for patients with GERD.	II
Maintenance therapy	
Most patients with GERD will require continuous therapy to control symptoms and to prevent complications.	I
Surgery	
Antireflux surgery represents a viable maintenance option for patients with an established diagnosis of GERD.	II
Refractory GERD	
GERD that is refractory to adequate acid suppression is uncommon. In these cases, the diagnosis should be confirmed through further diagnostic tests.	IV

[a]Level of evidence: I, strong evidence from at least one published systematic review of multiple, well-designed, randomized, controlled trials; II, strong evidence from at least one published, properly designed, randomized, controlled trial of appropriate size and in an appropriate clinical setting. III, strong evidence from published, well-designed trials without randomization, single group, pre–post, cohort, time series, or matched case-controlled studies; IV, evidence from well-designed nonexperimental studies from more than one center or research group or opinion of respected authorities, based on clinical evidence, descriptive studies, or reports of expert consensus committees.
Data from reference 4.

Promotility agents are not as effective as acid-suppression agents. Combining promotility agents with acid-suppression drugs offers only modest improvements in symptoms over standard doses of H_2-receptor antagonists and should not be routinely recommended. In addition, the availability of a promotility agent that has an acceptable adverse effect profile is lacking. Mucosal protectants, such as sucralfate, have a very limited role in the treatment of GERD.

Maintenance therapy is generally necessary to control symptoms and to prevent complications. For patients with more severe symptoms (with or without esophageal erosions) or for patients with other complications, maintenance therapy with a proton pump inhibitor is most effective. Routine use of combination therapy has no role in maintenance therapy of GERD. GERD that is refractory to adequate acid suppression is uncommon. In these cases, the diagnosis should be confirmed through further diagnostic tests before long-term, high-dose therapy or antireflux surgery are considered.[4]

NONPHARMACOLOGIC THERAPY

Nonpharmacologic treatment of GERD includes lifestyle modifications and antireflux surgery, which may be viable maintenance modalities in select patients. Endoscopic therapies, such as endoscopic sewing devices and endoluminal application of radiofrequency heat energy, have fallen out of favor and not routinely recommended.

Lifestyle Modifications

The most common lifestyle modifications that a patient should be educated about include weight loss in obese patients and elevation of the head of the bed, especially for those patients who have symptoms while in a recumbent position. Other lifestyle modifications should be individualized based for the patient's specific situation. These include consumption of smaller meals and not eating 3 hours prior to sleeping, avoidance of foods or medications that exacerbate GERD; smoking cessation, avoidance of tight-fitting clothes, and avoidance of alcohol (Table 39–4).

Obesity increases the risk of GERD, most likely through increased intraabdominal pressure and possibly by disruption of the esophagogastric junction.[12] A high-fat meal will decrease LES pressure for 2 hours or more postprandially. In contrast, a high-protein, low-fat meal will elevate LES pressure. Consequently, weight loss and a low-fat diet may help to improve GERD symptoms. Elevating the head of the bed approximately 6 to 8 inches with a foam wedge under the mattress (not just elevating the head with pillows) decreases nocturnal esophageal acid contact time and should be recommended. Many foods may worsen the symptoms of GERD. Fats and chocolate can decrease LES pressure, whereas citrus juice, tomato juice, coffee, and pepper may irritate damaged endothelium.

It is important to evaluate patient profiles and to identify potential medications that may exacerbate GERD symptoms. Medications, such as anticholinergics, barbiturates, calcium channel blockers, and theophylline decrease LES pressure. Other medications, including aspirin, iron, nonsteroidal antiinflammatory drugs, quinidine, potassium chloride, and bisphosphonates can act as direct contact irritants to the esophageal mucosa. Patients taking bisphosphonates (e.g., alendronate) should be instructed to drink 6 to 8 oz of plain tap water and remain upright for at least 30 minutes following administration. Proper patient education can help prevent dysphagia or esophageal ulceration. Patients should be closely monitored for worsening symptoms when any of these medications are started. If symptoms worsen, alternative therapies may be warranted. The clinician must weigh the risks and benefits of continuing a drug known to worsen GERD and esophagitis.

Smoking can cause aerophagia, which leads to increased belching and regurgitation. However, data are lacking to show that symptoms improve for patients who quit smoking. Nevertheless, patients with GERD should be encouraged to quit smoking. Alcohol, although not thought to play a role in severe disease, decreases LES pressure and may exacerbate symptoms such as heartburn.

Many patients are noncompliant with lifestyle modifications, and even those who do comply generally continue to have symptoms that require acid-suppression therapy. Nonetheless, it is important to regularly stress the potential benefits of lifestyle modifications that would benefit each individual patient.

Interventional Approaches

Interventional approaches include antireflux surgery and endoscopic therapies.

Antireflux Surgery 6 Surgical intervention is a viable maintenance alternative for select patients with well-documented GERD.[4] The goal of antireflux surgery is to re-establish the antireflux barrier, to position the lower esophageal sphincter within the abdomen where it is under positive (intraabdominal) pressure, and to close any associated hiatal defect. Antireflux surgery should be considered for patients (1) who fail to respond

TABLE 39-3 Therapeutic Approach to GERD in Adults

Patient Presentation	Recommended Treatment Regimen	Comments
Intermittent, mild heartburn	**Lifestyle modifications** **plus** **patient-directed therapy** Antacids • Maalox or Mylanta 30 mL as needed or after meals and at bedtime • Gaviscon 2 tabs after meals and at bedtime • Calcium carbonate 500 mg, 2–4 tablets as needed **and/or** Nonprescription H_2-receptor antagonists (taken up to twice daily) • Cimetidine 200 mg • Famotidine 10 mg • Nizatidine 75 mg • Ranitidine 75 mg **or** Nonprescription proton pump inhibitor (taken once daily) • Omeprazole 20 mg • Lansoprazole 15 mg	Lifestyle modifications should be individualized for each patient. Weight loss in obese patients and elevation of the head of the bed have been proven most beneficial. If symptoms are unrelieved with lifestyle modifications and nonprescription medications after 2 weeks, patient should seek medical attention.
Symptomatic relief of GERD	**Lifestyle modifications** **plus** **prescription-strength acid-suppression therapy** H_2-receptor antagonists (for 6–12 weeks) • Cimetidine 400 mg twice daily • Famotidine 20 mg twice daily • Nizatidine 150 mg twice daily • Ranitidine 150 mg twice daily **or** Proton pump inhibitors (for 4–8 weeks); all are given once daily • Dexlansoprazole 30 mg • Esomeprazole 20 mg • Lansoprazole 15 mg • Omeprazole 20 mg • Pantoprazole 40 mg • Rabeprazole 20 mg	For typical symptoms, treat empirically with prescription-strength acid-suppression therapy. If symptoms recur, consider maintenance therapy (MT). Note: Most patients will require standard doses for MT. Mild GERD can usually be treated effectively with H_2-receptor antagonists. Patients with moderate to severe symptoms should receive a proton pump inhibitor as initial therapy.
Healing of erosive esophagitis or treatment of patients presenting with moderate to severe symptoms or complications	**Lifestyle modifications** **Plus** Proton pump inhibitors for 4–16 weeks (up to twice daily) • Dexlansoprazole 60 mg daily • Esomeprazole 20–40 mg daily • Lansoprazole 30 mg daily • Omeprazole 20 mg daily • Rabeprazole 20 mg daily • Pantoprazole 40 mg daily **or** High-dose H_2-receptor antagonist (for 8–12 weeks) • Cimetidine 400 mg four times daily or 800 mg twice daily • Famotidine 40 mg twice daily • Nizatidine 150 mg four times daily • Ranitidine 150 mg four times daily	For atypical or alarm symptoms, obtain endoscopy (if possible) to evaluate mucosa. Give a trial of a proton pump inhibitor. If symptoms are relieved, consider MT. Proton pump inhibitors are the most effective maintenance therapy for patients with atypical symptoms, complications, and erosive disease. Patients not responding to pharmacologic therapy, including those with persistent atypical symptoms, should be evaluated via ambulatory reflux monitoring to confirm the diagnosis of GERD (if possible).
Interventional therapies	Antireflux surgery	

to pharmacologic treatment, (2) who opt for surgery despite successful treatment because of lifestyle considerations, including age, time, or expense of medications, (3) who have complications of GERD (e.g., Barrett esophagus, strictures), or (4) who have atypical symptoms and reflux documented with ambulatory pH monitoring. The antireflux surgical procedure chosen depends on the surgeon's expertise and preference, as well as on anatomic considerations. In general, 90% of patients have symptom resolution following successful Nissen fundoplication. The major complications with antireflux surgery include gas bloat syndrome (inability to belch or vomit), dysphagia, vagal denervation, splenic trauma, and, very rarely, death. In contrast, death has not occurred as a consequence of pharmacologic treatment with a proton pump inhibitor. Antireflux surgery is superior to medical management with an H_2-receptor antagonist or a promotility agent. In a 7-year follow-up study of omeprazole compared with antireflux surgery for patients with esophagitis, symptoms (regurgitation and heartburn) were better controlled in the surgical group; however treatment failures were also higher in the surgical group. In addition, more patients in the surgical group complained of complications, such as inability to belch, flatulence, and dysphagia.[13] Long-term effectiveness of antireflux surgery is uncertain.

Endoscopic Therapies Endoscopic approaches for the management of GERD have included endoscopic sewing devices and endoluminal application of radiofrequency heat energy resulting in tissue injury or nerve ablation (the Stretta procedure).[14,15] Unfortunately, results from these endoscopic therapies have proven

TABLE 39-4 Nonpharmacologic Treatment of GERD with Lifestyle Modifications

Recommended lifestyle modifications for all GERD patients
- Elevate the head of the bed (increases esophageal clearance). Use 6- to 8-inch blocks under the head of the bed. Sleep on a foam wedge.
- Weight reduction (reduces symptoms) in obese patients

Recommended lifestyle modifications that should be individualized to specific patients
- Avoid foods that may decrease lower esophageal sphincter pressure (fats, chocolate, alcohol, peppermint, and spearmint)
- Include protein-rich meals in diet (augments lower esophageal sphincter pressure)
- Avoid foods that have a direct irritant effect on the esophageal mucosa. (spicy foods, orange juice, tomato juice, and coffee)
- Behaviors that may reduce esophageal acid exposure
  - Eat small meals and avoid eating immediately prior to sleeping (within 3 hours if possible; Decreases gastric volume)
  - Stop smoking (decreases spontaneous esophageal sphincter relaxation)
  - Avoid alcohol (increases amplitude of the lower esophageal sphincter, peristaltic waves, and frequency of contraction)
  - Avoid tight-fitting clothes
  - Take drugs that have a direct irritant effect on the esophageal mucosa with plenty of liquid if they cannot be avoided (bisphosphonates, tetracyclines, quinidine, and potassium chloride, iron salts, aspirin, nonsteroidal antiinflammatory drugs)

Data from reference 4.

disappointing and are not routinely recommended. Emergence of natural orifice transluminal surgery (NOTES) and surgical techniques may evolve.

PHARMACOLOGIC THERAPY

Pharmacologic treatment consists of (1) patient-directed therapy with nonprescription antacids, H_2-receptor antagonists, or proton pump inhibitors and (2) prescription-strength acid-suppression therapy or promotility medications.

Patient-Directed Therapy

Patient-directed therapy, where patients self-treat themselves with nonprescription medications, is appropriate for mild, intermittent symptoms. Patients with continuous symptoms lasting longer than 2 weeks should seek medical attention.

Antacids and Antacid–Alginic Acid Products

Patients should be educated that antacids are an appropriate component of treating milder GERD symptoms, even though documentation of their efficacy in placebo-controlled clinical trials is lacking.[4] Although the literature is somewhat controversial on the superiority of antacids to placebo, clinicians and patients clearly consider antacids to be effective for immediate symptomatic relief, and antacids are often used concurrently with other acid-suppression therapies. Maintaining the intragastric pH >4 decreases the activation of pepsinogen to pepsin, a proteolytic enzyme. Also, neutralization of gastric fluid leads to increased LES pressure. Patients who require frequent use of antacids for chronic symptoms should be treated with prescription-strength acid-suppression therapy because their illness is considered more significant.

An antacid product combined with alginic acid is not a potent neutralizing agent and does not enhance LES pressure; however, it does form a highly viscous solution that floats on the surface of the gastric contents. This viscous solution is thought to serve as a protective barrier for the esophagus against reflux of gastric contents. It also reduces the frequency of the reflux episodes. The combination product may be superior to antacids alone in relieving the symptoms of GERD.[4] Efficacy data indicating endoscopic healing are lacking.

Antacid or antacid combination products may cause gastrointestinal adverse effects (diarrhea or constipation, depending on the product), alterations in mineral metabolism, and acid–base disturbances. Aluminum-containing antacids may bind to phosphate in the gut and lead to bone demineralization. In addition, antacids interact with a variety of medications by altering gastric pH, increasing urinary pH, adsorbing medications to their surfaces, providing a physical barrier to absorption, or forming insoluble complexes with other medications. Antacids have clinically significant drug interactions with tetracycline, ferrous sulfate, isoniazid, quinidine, sulfonylureas, and quinolone antibiotics. Antacid–drug interactions are influenced by composition, dose, dosage schedule, and formulation of the antacid.

Dosage recommendations for antacids in the management of GERD are somewhat difficult to derive from the literature. Doses range from hourly to an as-needed basis (Table 39–3). In general, antacids have a short duration of action, which necessitates frequent administration throughout the day to provide continuous neutralization of acid. Taking antacids after meals can increase the duration of action from about 1 hour to 3 hours; however, nighttime acid suppression cannot be maintained with bedtime doses.

Nonprescription H_2-Receptor Antagonists and Proton Pump Inhibitors

Nonprescription H_2-receptor antagonists (cimetidine, famotidine, nizatidine, and ranitidine) are effective in diminishing gastric acid secretion when taken prior to meals and decrease GERD symptoms associated with exercise. Antacids may have a slightly faster onset of action, while the H_2-receptor antagonists have a much longer duration of action compared with antacids.

The proton-pump inhibitor omeprazole is available without a prescription. A dose of 20 mg/day is indicated for short-term treatment of heartburn. Lansoprazole 15 mg gives patients a second option in the proton pump inhibitor class that is now available without a prescription. Patients who do not respond to lifestyle modifications and patient-directed therapy after 2 weeks should be seen by their clinician.

Acid-Suppression Therapy

7 Acid-suppression therapy with prescription-strength H_2-receptor antagonists and proton pump inhibitors are the mainstay of GERD treatment.

H_2-Receptor Antagonists (Cimetidine, Famotidine, Nizatidine, and Ranitidine) H_2-Receptor antagonists in divided doses are effective in treating patients with mild to moderate GERD.[4] The majority of the trials assessing the efficacy of standard doses of H_2-receptor antagonists indicate that symptomatic improvement is achieved in an average of 60% of patients after 12 weeks of therapy.[4] However, endoscopic healing rates tend to be lower, an average of 50% of patients at 12 weeks.[4]

The efficacy of H_2-receptor antagonists in the management of GERD is extremely variable and is frequently lower than desired. Response to the H_2-receptor antagonists is dependent on the (1) severity of disease, (2) dosage regimen used, and (3) duration of therapy. These factors are important to keep in mind when comparing clinical trials and/or assessing a patient's response to therapy. The severity of esophagitis at baseline has a profound impact on the patient's response to H_2-receptor antagonists. For symptomatic relief of mild GERD, low-dose, nonprescription H_2-receptor antagonists or standard doses given twice daily may be beneficial. Patients who do not respond to standard doses may

be hypersecreters of gastric acid and will require higher doses. Although higher doses of H_2-receptor antagonists may provide higher symptomatic and endoscopic healing rates, limited information exists regarding the safety of these regimens, and they can be less effective and more costly than once daily proton pump inhibitors. Unlike duodenal ulcer disease, in which the duration of therapy is relatively short (e.g., 4 to 6 weeks), prolonged courses of H_2-receptor antagonists are frequently required in the treatment of GERD.

Because all of the H_2-receptor antagonists have similar efficacy, selection of the specific agent to use in the management of GERD should be based on factors such as differences in pharmacokinetics, safety profile, and cost. In general, the H_2-receptor antagonists are well tolerated. The most common adverse effects are headache, somnolence, fatigue, dizziness, and either constipation or diarrhea. Patients should be monitored for the presence of adverse effects as well as potential drug interactions, especially when on cimetidine. Cimetidine may inhibit the metabolism of theophylline, warfarin, phenytoin, nifedipine, and propranolol, among others. An alternate H_2-receptor antagonist should be selected if the patient is on any of these medications.

Proton Pump Inhibitors (Dexlansoprazole, Esomeprazole, Lansoprazole, Omeprazole, Pantoprazole, and Rabeprazole) Proton pump inhibitors are superior to H_2-receptor antagonists in treating patients with moderate to severe GERD. This includes not only those patients with esophageal tissue injury (e.g., Barrett esophagus, strictures, or esophagitis), but also those patients with symptom-based GERD syndromes. A few trials have compared proton pump inhibitors with each other. In general, healing rates at 4 weeks and 8 weeks are similar; lansoprazole and rabeprazole, however, may relieve symptoms faster after the first dose when compared with omeprazole. Healing rates at 4 weeks and 8 weeks were similar. Symptomatic relief is seen in approximately 83% of patients with endoscopic evidence of injury after 8 weeks treated with a proton pump inhibitor, whereas the endoscopic healing rate at 8 weeks is 78%.[4] Proton pump inhibitors block gastric acid secretion by inhibiting gastric H^+/K^+-adenosine triphosphatase in gastric parietal cells.[16] This produces a profound, long-lasting antisecretory effect capable of maintaining the gastric pH >4, even during postprandial acid surges. A correlation appears to exist between the percentage of time the gastric pH remains >4 during the 24-hour period and healing erosive esophagitis.

The proton pump inhibitors are usually well-tolerated. Potential adverse effects include headache, dizziness, somnolence, diarrhea, constipation, nausea, and vitamin B_{12} deficiency. The frequency of adverse events appears to be similar to that seen with the H_2-receptor antagonists. Of recent concern is the role proton pump inhibitors may play in the acquisition of *Clostridium difficile* infection during acid suppression. Acid suppression may result in loss of host defense against ingested spores and bacteria permitting a higher burden of exposure.[17,18] Patient selection is important to minimize this risk.

Drug interactions with the proton pump inhibitors vary slightly with each agent. All proton pump inhibitors can decrease the absorption of drugs such as ketoconazole or itraconazole, which require an acidic environment to be absorbed. All proton pump inhibitors are metabolized by the cytochrome P450 system to some extent, specifically by the CYP2C19 and CYP3A4 enzymes. While, no interactions with lansoprazole, pantoprazole, or rabeprazole have been seen with CYP2C19 substrates such as diazepam, warfarin, and phenytoin, concerns have been raised regarding the concomitant use of proton pump inhibitors, especially omeprazole, with clopidogrel.[19,20] Clopidogrel, a prodrug, is converted to its active metabolite via the CYP2C19 and CYP3A4 enzyme. Inhibition of CYP2C19 by proton pump inhibitors may decrease the effectiveness of clopidogrel causing cardiovascular adverse events. Further evaluation is needed to determine the extent of this drug interaction and the role polymorphic gene variation may play in patients on clopidogrel. In the mean time, careful review of the risk-to-benefit profile regarding the use of proton pump inhibitors for patients on clopidogrel should be considered. Using an alternative agent, such as an H_2-receptor antagonist may be prudent in this patient population.

CLINICAL CONTROVERSY

It is unclear which, if any, proton pump inhibitor is preferred for patients taking clopidogel due to potential drug interactions. Even pantoprazole, which does not affect CYP2C19, appears to have decrease the effectiveness of clopidogrel. Other mechanisms for this interaction have not been clearly established.

Esomeprazole does not appear to interact with warfarin or phenytoin, and an interaction with diazepam is generally not considered clinically relevant. Pantoprazole is also metabolized by a cytosolic sulfotransferase and is therefore less likely to have significant drug interactions compared with the other proton pump inhibitors. Although generally not a problem, omeprazole has the potential to inhibit the metabolism of warfarin, diazepam, and phenytoin, and lansoprazole may decrease theophylline concentrations. Patients taking warfarin should be monitored for potential bleeding. Drug interactions with omeprazole are of particular concern for patients who are considered "slow metabolizers" of omeprazole, which is more common in the Asian population but also found in approximately 3% of the caucasian population. Unfortunately, it is unclear which patients have the polymorphic gene variation that makes them slow metabolizers. Like omeprazole, the metabolism of esomeprazole may also be altered for patients with this polymorphic gene variation. Patients on potentially interacting drugs, such as warfarin, should be monitored closely for potential problems.

The proton pump inhibitors degrade in acidic environments and are therefore formulated in a delayed-release capsule or tablet formulation. Lansoprazole, esomeprazole, and omeprazole contain enteric-coated (pH-sensitive) granules in a capsule form. For patients who are unable to swallow the capsule or for pediatric patients, the contents of the delayed-release capsule can be mixed in applesauce or placed in orange juice. If a patient has a nasogastric tube, the contents of an omeprazole capsule can be mixed in 8.4% sodium bicarbonate solution. Esomeprazole granules can be dispersed in water. Lansoprazole comes in a packet for oral suspension and a delayed-release, orally disintegrating tablet. Although these dosage forms are beneficial for those who cannot swallow the capsule, such as elderly or pediatric patients, the packet for oral suspension should not be placed through a nasogastric tube. Patients taking pantoprazole or rabeprazole should be instructed not to crush, chew, or split the delayed-release tablets. Lansoprazole, esomeprazole, and pantoprazole are available in an intravenous formulation, which offers an alternative route of administration for patients who are unable to take an oral proton pump inhibitor. Importantly, the intravenous product is not more efficacious than oral proton pump inhibitors and is significantly more expensive. Careful patient selection is necessary to avoid the increased cost from the use of the intravenous product.

The newest dosage form of omeprazole is in a delayed-release tablet and a combination product with sodium bicarbonate in an immediate-release capsule and oral suspension (Zegerid). It is the first immediate-release proton pump inhibitor and should be taken on an empty stomach at least 1 hour before a meal. Zegerid offers an alternative to the delayed-release capsules or the intravenous formulation in adult patients with a nasogastric tube.

Dexlansoprazole is the newest proton pump inhibitor approved by the FDA. The capsule is a dual delayed-release formulation, with the first release occurring 1 to 2 hours after the dose and the second release occurring 4 to 5 hours after the dose. The clinical significance of this dual release is not known.

Patients should be instructed to take their proton pump inhibitor in the morning, 15 to 30 minutes before breakfast, to maximize efficacy, because these agents inhibit only actively secreting proton pumps. Dexlansoprazole can be taken without regards to meals. Patients with nocturnal symptoms may benefit from taking their proton pump inhibitor prior to the evening meal. If dosed twice daily, the second dose should be administered approximately 10 to 12 hours after the morning dose and prior to a meal or snack.

Promotility Agents

Promotility agents may be useful as an adjunct to acid-suppression therapy for patients with a known motility defect (e.g., LES incompetence, decreased esophageal clearance, delayed gastric emptying). Unfortunately, all available promotility agents are fraught with undesirable side effects and are not generally as effective as acid-suppression therapy. Extrapyramidal effects, sedation, and irritability are common with bethanechol and metoclopramide.

Cisapride Cisapride has comparable efficacy to H_2-receptor antagonists in treating patients with mild esophagitis. Unfortunately, cisapride is no longer available for routine use because of life-threatening cardiac arrhythmias when it is combined with certain medications and other disease states. It is currently available only through a limited access program from the manufacturer.

Metoclopramide Metoclopramide, a dopamine antagonist, increases LES pressure in a dose-related manner, and accelerates gastric emptying in gastroesophageal reflux patients. Unlike cisapride, however, metoclopramide does not improve esophageal clearance. Metoclopramide provides symptomatic improvement for some patients with gastroesophageal reflux disease; however, substantial data indicating that metoclopramide provides endoscopic healing are lacking. In addition, metoclopramide's side-effect profile and the incidence of tachyphylaxis with continued use limits its usefulness in treating many patients with GERD. The risk of adverse effects is much greater for elderly patients and for patients with renal dysfunction because the drug is primarily eliminated by the kidneys. Contraindications include Parkinson disease, mechanical obstruction, concomitant use of other dopamine antagonists or anticholinergic agents, and pheochromocytoma.

Bethanechol Bethanechol, a promotility drug, has limited value in the treatment of GERD because of unwanted side effects. Bethanechol is not routinely recommended for the treatment of GERD.

Other Promotility Drugs Under Investigation Other promotility drugs under investigation include domperidone, a dopamine antagonist, itopride, and baclofen. Because domperidone does not cross the blood–brain barrier, it does not cause the central nervous system effects seen with metoclopramide. However, it is not currently available in the United States. Baclofen, an aminobutyric acid (GABA) receptor type B agonist, may decrease esophageal acid exposure and the number of reflux episodes by decreasing the number of transient relaxations of the LES. However, this agent has many side effects, limiting its usefulness in GERD.

Mucosal Protectants

Sucralfate, a nonabsorbable aluminum salt of sucrose octasulfate, has very limited value in the treatment of GERD. Sucralfate is not routinely recommended for use in the treatment of GERD.

Combination Therapy

Combination therapy with an acid-suppression agent and a promotility agent or a mucosal protectant agent would seem logical given the multifactorial nature of the disease, particularly in light of the disappointing results seen with many monotherapy regimens. However, sufficient data to support combination therapy are limited, and this approach should not be routinely recommended unless a patient has GERD plus motor dysfunction occurring. The addition of an H_2-receptor antagonist at bedtime to proton pump inhibitor therapy for the treatment of nocturnal symptoms has been evaluated. The effectiveness of this strategy may decrease over time due to tachyphylaxis with H_2-receptor antagonists.[21]

Maintenance Therapy

8 Although healing and/or symptomatic improvement may be achieved via many different therapeutic modalities, a large percentage of patients with gastroesophageal reflux will relapse following discontinuation of therapy, especially those with more severe disease. Patients who have symptomatic relapse following discontinuation of therapy or lowering of dose, including patients with complications such as Barrett esophagus, strictures, or esophagitis, should be considered for long-term maintenance therapy to prevent complications or worsening of esophageal function.[4] The goal of maintenance therapy is to improve quality of life by controlling the patient's symptoms and preventing complications. These goals cannot generally be achieved by decreasing the dose of the therapeutic modality used for initial healing or switching to a less potent acid-suppression agent. Most patients will require standard doses to prevent relapses. Patients should be counseled on the importance of complying with lifestyle changes and long-term maintenance therapy in order to prevent recurrence or worsening of disease.[4]

H_2-Receptor antagonists may be effective maintenance therapy for patients with mild disease.[4] The proton pump inhibitors are the drugs of choice for maintenance treatment of moderate to severe esophagitis or symptoms. Low doses of a proton pump inhibitor or alternate-day dosing may be effective in some patients with milder symptoms, thereby allowing titration in some cases. "On-demand" maintenance therapy, by which patients take their proton pump inhibitor only when they have symptoms, may be effective for patients with endoscopy-negative GERD.[4] Although not well studied, many patients with only mild to moderate symptoms may decide on their own to take their medication this way for the financial benefit. However, patients with more-persistent symptoms and/or complications should be maintained on standard doses of proton pump inhibitors.

Long-term chronic use of proton pump inhibitor doses higher than standard treatment doses is not indicated unless the patient has complicated symptoms, has erosive esophagitis per endoscopy, or has had further diagnostic evaluation to determine the level of acid exposure. Metoclopramide is not approved for maintenance therapy, and use is limited by adverse-effect profile. Antireflux surgery may also be considered a viable alternative to long-term drug therapy for maintenance of healing for patients who are candidates.

Maintenance Therapy with H_2—Receptor Antagonists The studies evaluating the efficacy of the H_2-receptor antagonists in maintaining GERD patients in remission have been disappointing. Currently, ranitidine 150 mg twice daily is the only H_2-receptor antagonist regimen that is FDA approved for maintenance of healing of erosive esophagitis.

Maintenance Therapy with Proton Pump Inhibitors Long-term use of the proton pump inhibitors are relatively safe, with no evidence of carcinoid tumors directly linked to their use. Prolonged hypergastrinemia leading to the development of colonic polyps, and potentially adenocarcinoma, was also a concern that has proven unfounded with long-term use.[22] However, the role of *Helicobacter pylori* status for patients with GERD has been questioned. As a consequence of the controversy surrounding *H. pylori* and GERD, specific guidelines on how to handle these patients are lacking. Most clinicians would probably opt to eradicate *H. pylori* infections once detected. Further studies are needed to determine the role of *H. pylori* for patients with GERD. Concern has been raised about the long-term use of proton pump inhibitors and the increased risk of bone fractures.[23] Data are conflicting, but the proposed mechanism is through inhibition by the H^+/K^+-ATPase pump indirectly inhibiting bone resorption. In addition, the increased pH may decrease calcium absorption, thereby putting patients at greater risk for fractures.[24,25]

SPECIAL POPULATIONS

There are several special populations that should be considered when discussing GERD, such as patients with atypical symptoms, pediatric patients, elderly patients, and patients with refractory symptoms.

PATIENTS WITH EXTRAESOPHAGEAL (ATYPICAL) GERD

Patients presenting with atypical symptoms may require higher doses and longer treatment courses as compared with patients with typical symptoms. Patients with suspected reflux chest pain syndrome may benefit from an empiric course of twice daily proton pump inhibitor therapy for 4 weeks once cardiac work up is known to be negative.[1] If symptoms continue, patients should be evaluated with manometry, ambulatory pH, or impedance-pH monitoring to rule out dysmotility or refractory symptoms.[1] Because there are many causes of asthma and laryngeal symptoms, a concomitant esophageal GERD syndrome must also be present to associate these symptoms with GERD. In practice, these patients may benefit from twice daily proton pump inhibitor for 3 to 4 months even though evidence supporting this regimen is not well established.[1] This recommendation is based more on pH monitoring data showing normalization of gastric pH with twice daily dosing.[1] For patients not responding to empiric therapy, pH monitoring may be beneficial in determining acid exposure as it relates to symptoms. The optimal dose of proton pump inhibition is not well-defined. Maintenance therapy is generally indicated for patients who respond to the therapeutic trial or have endoscopic evidence of reflux. Antireflux surgery may be an option in select patients. Without a concomitant esophageal GERD syndrome, acid-suppressing therapy is not well supported for patients with laryngitis or asthma symptoms.

PEDIATRIC PATIENTS WITH GERD

Many infants have physiologic reflux with little or no clinical consequence. Uncomplicated gastroesophageal reflux usually manifests as regurgitation or "spitting up" and resolves without incident by 12 to 14 months of life.[26] It usually responds to supportive therapy, including dietary adjustments, postural management, and reassurance for the parents. Thickened feedings may be useful in milder cases. While this does not decrease the time the pH is <4, it may decrease the incidence of regurgitation.[26] Chronic vomiting associated with gastroesophageal reflux must be distinguished from other causes, such as neurologic, metabolic, eating, and rumination disorders. Smaller, more frequent feedings may be beneficial. In formula-fed infants, an extensively hydrolyzed protein may help identify milk protein sensitivity as the cause of unexplained vomiting and crying.[26] Developmental immaturity of the LES is one suspected cause of gastroesophageal reflux in infants.[26] Like adults, transient LES relaxations seem to be the most common cause of gastroesophageal reflux in children. Other causes include impaired luminal clearance of gastric acid, neurologic impairment, and type of infant formula. Complications, although rare, include distal esophagitis, failure to thrive, esophageal peptic strictures, Barrett esophagus, and pulmonary disease.

The benefits of using a promotility medication, such as metoclopramide, erythromycin, domperidone, bethanachol, and baclofen, are outweighed by the potential adverse effects that may occur and, therefore, cannot be routinely recommended.[26] Ranitidine is commonly used at a dose of 2 mg/kg twice daily.[26] Tachyphylaxis may develop making the effectiveness of H_2-receptor antagonsists less than optimal. The use of proton pump inhibitor use in children is increasing, especially in those with esophagitis. Most patients will respond to once daily proton pump inhibiter dosing. Lansoprazole, esomeprazole and omeprazole are indicated for treating symptomatic and erosive GERD for pediatric patients older than age 1 year. Lanzoprazole 15 mg once daily is recommended for children who weigh 30 kg or less, and a dose of 30 mg once daily is recommended for those who weigh more than 30 kg. Esomeprazole may be dosed 10 to 20 mg daily for children 1 to 11 years old and 20 to 40 mg daily for children 12 to 17 years old. Omeprazole 5 mg daily may be used in children weighing between 5 to 10 kg, 10 mg for children weighing between 10 to 20 kg and 20 mg daily for children weighing >20 kg. Even though no major adverse events have been noted in children receiving proton pump inhibitors for up to 7 years, the relative safety of prolonged proton pump inhibitor use in children remains unknown.[27] Long-term use of a proton pump inhibitor without a clear diagnosis of GERD is not recommended.[26]

ELDERLY PATIENTS WITH GERD

Many elderly patients have decreased host defense mechanisms, such as saliva production. More aggressive therapy with a proton pump inhibitor may be warranted for patients older than 60 years of age with symptomatic GERD. Often these patients do not seek medical attention because they feel their symptoms are part of the normal aging process. They may also present with atypical symptoms such as chest pain, asthma, poor dentition, or jaw pain. Decreased GI motility is a common problem in elderly patients. Unfortunately, there are no good promotility agents available to these patients. Elderly patients are especially sensitive to the central nervous system effects of metoclopramide. They may also be sensitive to the central nervous system effects of H_2-receptor antagonists. Proton pump inhibitors appear to be the most useful treatment modality because they have superior efficacy and are dosed once daily, which is beneficial in all patients, but is especially beneficial in the elderly. Long-term risk of bone fractures may be of concern in this population. Patients at risk for bone fractures should be monitored appropriately.

PATIENTS WITH REFRACTORY GERD

GERD refractory to medical management is rare. Other causes for the patient's symptoms should be evaluated. The majority of patients with refractory symptoms experience nocturnal acid

breakthrough. Other reasons for refractory symptoms may be related to timing of proton pump inhibitor and drug metabolism differences in certain patients. Because of this, switching to another proton pump inhibitor may be effective for refractory symptoms in some patients. Ambulatory pH monitoring is useful for patients who are not responding to therapy. Adding an H_2-receptor antagonist at bedtime for nocturnal symptoms has been suggested; however, the effect may be short-lived.[21] Antireflux surgery may also be considered in this patient population.

PHARMACOECONOMIC CONSIDERATIONS

In addition to the traditional clinical endpoints that demonstrate that a certain therapy is effective, the cost effectiveness of the therapy in relation to predicted outcomes and its effects on quality of life must be evaluated. For GERD, one must consider the primary goals of treatment: to relieve symptoms, to heal injury, to prevent recurrence, and to prevent complications. These factors must be evaluated separately, because different costs are associated with achieving each end point. For example, patients with complications associated with GERD, such as strictures, would be more likely to use medical resources as a consequence of revisits and diagnostic tests. Although effects on quality of life may be difficult to evaluate when your goal is preventing recurrence, untreated GERD has a more negative impact on psychological well-being than untreated hypertension, mild heart failure, angina pectoris, or menopause. Improving a patient's quality of life is a measure of treatment success and may help decide which therapy a patient receives.

The proton pump inhibitors are generally more expensive than the H_2-receptor antagonists or promotility agents. Omeprazole's generic availability and nonprescription availability of omeprazole and lansoprazole makes this less of an issue. However, the most expensive therapy is the one that is ineffective. If the H_2-receptor antagonist does not accomplish the treatment goals, then it costs more because the patient must be retreated.

Patient compliance is another factor that affects the outcome of drug therapy. Drug regimens that are easily managed improve compliance, and thus improve outcome for the patient. This especially can be a problem for patients who require high-dose therapy with H_2-receptor antagonists. Not only is the patient required to take the drug more often in higher doses, but there is also increased expense associated with such regimens. The patient may be unable to afford the drug. Choosing a drug that is least expensive and provides the greatest benefit related to dosing interval and number of tablets taken is the optimal regimen. Studies comparing various treatment strategies for GERD show that proton pump inhibitors are more cost-effective than H_2-receptor antagonists, especially for patients with moderate to severe disease.

Decision analysis has been used to evaluate the cost-effectiveness of lifestyle modifications and/or patient-directed therapy alone or combined with omeprazole 20 mg daily or ranitidine 150 mg twice daily for patients with persistent symptomatic GERD. A complex model that evaluated the influence of empiric versus definitive therapy, compliance, and efficacy of the three treatment regimens was employed. Although the retail cost of omeprazole was highest among the treatments evaluated, it was the most cost-effective strategy and was associated with the lowest overall cost. Studies also show that proton pump inhibitors improve quality-of-life measures in symptomatic patients with erosive esophagitis.[28] Additional studies are needed to evaluate the impact of various treatment regimens on quality-of-life issues and cost, and to compare long-term medical management with antireflux surgery and endoscopic therapies.

EVALUATION OF THERAPEUTIC OUTCOMES

9 The long-term benefits of treatment are difficult to assess because of the limited information known about the epidemiology and natural history of GERD. Consequently, successful outcomes are generally measured in terms of three separate end points: (1) relieving symptoms, (2) healing the injured mucosa, and (3) preventing complications.

The short-term goal of therapy is to relieve symptoms such as heartburn and regurgitation to the point at which they do not impair the patient's quality of life. Patients should be educated regarding specific lifestyle modifications that are applicable to their individual situation including weight loss, raising the head of the bed, smoking cessation, eating smaller meals, and avoiding eating prior to bedtime. Patients should also be instructed to avoid or limit foods that aggravate GERD symptoms, such as fat and chocolate. In addition, the patient's drug profile should be reviewed to identify medications that may contribute to GERD symptoms. These agents should be avoided if possible. Table 39–5 has recommendations for providing pharmaceutical care to patients with GERD.

The clinician should take an active role in educating the patient about potential adverse effects and drug interactions that may occur with drug therapy. The frequency and severity of symptoms should be monitored and patients should be counseled on symptoms that suggest the presence of complications requiring immediate medical attention, such as dysphagia or odynophagia. Patients should also be monitored for the presence of atypical symptoms such as laryngitis asthma or chest pain. These symptoms require further diagnostic evaluation. Long-term maintenance treatment is indicated for patients who have strictures because the strictures commonly recur if reflux esophagitis is not treated.

The second goal is to heal the injured mucosa. Again, individualized lifestyle modifications and the importance of complying with the therapeutic regimen chosen to heal the mucosa should be stressed. Patients should be educated about the risk of relapse and the need for long-term maintenance therapy to prevent recurrence or complications.

TABLE 39-5 Recommendations for Providing Pharmaceutical Care to Patients with GERD

1. Assess the patient's symptoms to determine if patient-directed therapy is appropriate or whether patient should be evaluated by a clinician. Determine the type of symptoms, frequency, and exacerbating factors. Refer any patient with alarm or atypical symptoms to a clinician for further diagnostic workup.
2. Obtain a thorough history of prescription, nonprescription, and natural drug product use.
3. Counsel the patient on lifestyle modifications that will improve symptoms.
4. Recommend appropriate drug therapy based on patient presentation.
5. Develop a plan to assess effectiveness of acid-suppression therapy after an appropriate amount of time (8–16 weeks). Recommend alternative therapy if necessary.
6. Assess improvement in quality-of-life measures such as physical, psychologic, and social functioning and well-being.
7. Evaluate patient for the presence of adverse drug reactions, allergies, and drug interactions.
8. Stress the importance of compliance with the therapeutic regimen, including lifestyle modifications. Recommend a therapeutic regimen that is easy for the patient to accomplish.
9. Provide patient education with regard to disease state, lifestyle modifications, and drug therapy. Patients should be counseled on
   - What causes GERD and what things to avoid
   - When to take their medications
   - What potential adverse effects or drug interactions may occur
   - What alarm signs they should report to their clinician

The final, more long-term goal of therapy is to decrease the risk of complications (esophagitis, strictures, Barrett esophagus, and esophageal adenocarcinoma). A small subset of patients may continue to fail treatment despite therapy with high doses of H_2-receptor antagonists or a proton pump inhibitor. Patients should be monitored for the presence of continual pain, dysphagia, or odynophagia.

ABBREVIATIONS

GERD: gastroesophageal reflux disease

GI: gastrointestinal

H_2: histamine type-2

LES: lower esophageal sphincter

CHAPTER 40

Peptic Ulcer Disease

ROSEMARY R. BERARDI AND RANDOLPH V. FUGIT

KEY CONCEPTS

1. Patients with peptic ulcer disease (PUD) should reduce psychological stress, cigarette smoking, and nonsteroidal antiinflammatory drug (NSAID) use and avoid foods and beverages that exacerbate ulcer symptoms.
2. Eradication is recommended for all *Helicobacter pylori* (*H. pylori*)–positive patients with an active ulcer, a documented history of a prior ulcer, or a history of ulcer-related complications.
3. The selection of an *H. pylori* eradication regimen should be based on efficacy, safety, antibiotic resistance, cost, and the likelihood of medication adherence. Treatment should be initiated with a proton pump inhibitor (PPI)–based three-drug regimen. If a second course of *H. pylori* therapy is required, the regimen should contain different antibiotics.
4. PPI cotherapy reduces the risk of NSAID-related gastric and duodenal ulcers and is at least as effective as recommended dosages of misoprostol and superior to the histamine-2 receptor antagonists (H_2RA).
5. Standard PPI dosages and a nonselective NSAID are as effective as a selective cyclooxygenase-2 (COX-2) inhibitor in reducing the risk of NSAID-induced ulcers and upper gastrointestinal (GI) complications.
6. The eradication of *H. pylori* improves clinical outcomes and decreases the use of healthcare resources when compared with conventional antisecretory therapy. The cost effectiveness of misoprostol cotherapy is greatest for patients with the highest risk for GI complications. Cotherapy with PPIs and NSAIDs or selective COX-2 inhibitors is cost effective even in low-risk patients especially if the least costly PPI is used.
7. Patients with PUD, especially those receiving *H. pylori* eradication or misoprostol cotherapy, require patient education regarding their disease and drug treatment to successfully achieve a positive therapeutic outcome.
8. The recommended treatment for severe peptic ulcer bleeding after appropriate endoscopic treatment is the intravenous administration of a PPI loading dose followed by a 72-hour continuous infusion with a goal of maintaining an intragastric pH of 6 or greater.
9. Critically ill patients at the highest risk of developing stress-related mucosal bleeding (SRMB) who require prophylactic drug therapy include those with respiratory failure on mechanical ventilation or those with coagulopathy.
10. There are limited data to support the selection of a PPI over an intravenous H_2RA for SRMB prophylaxis. The decision should be based upon appropriate individual patient characteristics (e.g., nothing by mouth, presence of nasogastric tube, renal failure).

PEPTIC ULCER DISEASE

Acid-related diseases (gastritis, erosions, and peptic ulcer) of the upper gastrointestinal (GI) tract require gastric acid for their formation.[1–3] Peptic ulcer disease (PUD) differs from gastritis and erosions in that ulcers typically extend deeper into the muscularis mucosa.[1] There are three common forms of peptic ulcers: *Helicobacter pylori* (*H. pylori*)-positive, nonsteroidal antiinflammatory drug (NSAID)-induced, and stress ulcers (Table 40–1). The term *stress-related mucosal damage* (SRMD) is preferred to stress ulcer or stress gastritis, because the mucosal lesions range from superficial gastritis and erosions to deep ulcers.

H. pylori–positive and NSAID-induced ulcers are chronic peptic ulcers that differ in etiology, clinical presentation, and tendency to recur (see Table 40–1). These ulcers develop most often in the stomach and duodenum of ambulatory patients (Fig. 40–1). Occasionally, ulcers develop in the esophagus, jejunum, ileum, or colon. The natural course of chronic PUD is characterized by frequent ulcer recurrence. The most important factors that influence ulcer recurrence are *H. pylori* infection and NSAID use. Other factors include cigarette smoking, alcohol use, ulcer-related complications, gastric acid hypersecretion, and patient noncompliance. The cause of ulcer recurrence is most likely multifactorial.

Peptic ulcers are also associated with Zollinger-Ellison syndrome (ZES), radiation, chemotherapy, vascular insufficiency, and other chronic diseases (Table 40–2).[1,3] Although a strong association exists between chronic pulmonary diseases, chronic renal failure, and cirrhosis, the pathophysiologic mechanisms of these associations remain unclear.[1] In contrast, SRMD occurs primarily in the stomach in critically ill patients (see Table 40–1).[1]

This chapter focuses on chronic PUD associated with *H. pylori* and NSAIDs. A brief discussion of ZES and upper GI bleeding related to PUD and SRMD is included.

TABLE 40-1 Comparison of Common Forms of Peptic Ulcer

Characteristic	*H. pylori* Induced	NSAID Induced	SRMD
Condition	Chronic	Chronic	Acute
Site of damage	Duodenum > stomach	Stomach > duodenum	Stomach > duodenum
Intragastric pH	More dependent	Less dependent	Less dependent
Symptoms	Usually epigastric pain	Often asymptomatic	Asymptomatic
Ulcer depth	Superficial	Deep	Most superficial
GI bleeding	Less severe, single vessel	More severe, single vessel	More severe, superficial mucosal capillaries

H. pylori, Helicobacter pylori; NSAID, nonsteroidal antiinflammatory drug; SRMD, stress-related mucosal damage.

EPIDEMIOLOGY

The epidemiology of PUD is complicated and difficult to estimate given the variablity in the prevalence of *H. pylori* infection, NSAID use, and cigarette smoking as well as the various methods used to detect ulcers, e.g., endoscopy, radiology, symptoms, or complications.[1,4] The prevalence and incidence of PUD in the United States also reflects improvements in drug therapy, the dramatic shift to ambulatory management, and changes in the criteria and coding system for mortality and hospitalization data.[1] Recent trends suggest a shift from predominance in men to a similar occurrence in men and women with increasing rates of disease in older individuals and a decrease in the younger population.[1,4] Despite a modest decline in mortality, hospitalizations, and office visits, PUD remains one of the most common GI diseases, resulting in impaired quality of life, work loss, and high-cost medical care.

ETIOLOGY AND RISK FACTORS

Most peptic ulcers occur in the presence of acid and pepsin when *H. pylori*, NSAIDs, or other factors (see Table 40–2) disrupt the normal mucosal defense and healing mechanisms.[1] Hypersecretion of acid is the primary pathogenic mechanism in hypersecretory states such as ZES.[3] Benign gastric ulcers can occur anywhere in the stomach, although most are located on the lesser curvature, just distal to the junction of the antral and acid-secreting mucosa (see Fig. 40–1). Most duodenal ulcers occur in the first part of the duodenum (duodenal bulb).

HELICOBACTER PYLORI

H. pylori infection causes chronic gastritis in infected individuals and is causally linked to PUD, mucosa-associated lymphoid tissue (MALT) lymphoma, and gastric cancer (Fig. 40–2).[1,2,5–8] The majority of infected individuals remain asymptomatic, but 10% to 20% will develop PUD during their lifetime and about 1% will develop gastric cancer.[1,2,8] Host-specific cofactors and *H. pylori* strain variability play an important role in the pathogenesis of PUD and gastric cancer.[2,8] Although an association between *H. pylori* and PUD bleeding is less clear, there is evidence that eradication of *H. pylori* decreases recurrent bleeding.[5,9] No specific link has been established between *H. pylori* and dyspepsia, nonulcer dyspepsia (NUD), or gastroesophageal reflux disease (GERD).[5,9–11] However, some patients with dyspepsia and NUD may benefit from *H. pylori* eradication.[5,9] Although eradication of *H. pylori* may worsen GERD symptoms in some patients, eradication should not be withheld.[5,10] An association between *H. pylori* infection and iron deficiency anemia has been established, but cause and effect has not been proven, and whether *H. pylori* eradication is beneficial is uncertain.[5,11] There are insufficient data to support a link between *H. pylori* and extragastric manifestations including cardiovascular, hematologic, respiratory, hepatobiliary, and neurologic diseases.[5,11]

The prevalence of *H. pylori* varies by geographic location, socioeconomic conditions, ethnicity, and age. In developing countries, *H. pylori* prevalence is more common than in industrialized countries and correlates with lower socioeconomic levels.[2,5,6] The prevalence of *H. pylori* in the United States is 30% to 40% but is much higher in individuals over 60 years (50% to 60%) than in children under 12 years (10% to 15%) of age.[2,5] Although most individuals in the United States acquire *H. pylori* in childhood, the rate of acquisition in children is declining and most likely will continue to fall as a consequence of improved socioeconomic conditions.[2] Caucasians are infected with *H pylori* less frequently than African Americans and Hispanic persons, but this is thought to be related to lower socioecomonic status and living conditions. Infection rates do not differ with gender or smoking status.

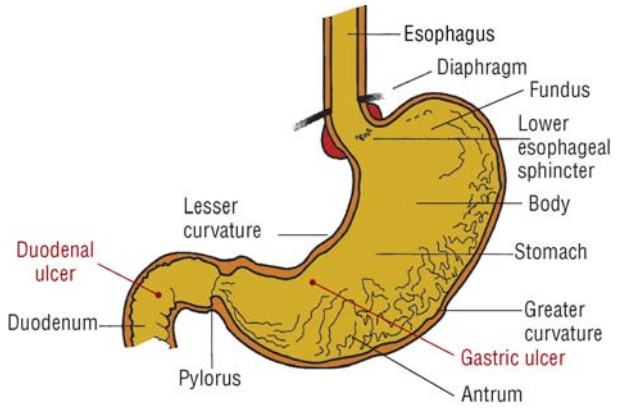

FIGURE 40-1. Anatomic structure of the stomach and duodenum and most common locations of gastric and duodenal ulcers.

TABLE 40-2 Potential Causes of Peptic Ulcer

- Common causes
  - *Helicobacter pylori* infection
  - Nonsteroidal antiinflammatory drugs
  - Critical illness (stress-related mucosal damage)
- Uncommon causes of chronic peptic ulcer
  - Idiopathic (non-*H. pylori*, non-NSAID peptic ulcer)
  - Hypersecretion of gastric acid (e.g., Zollinger-Ellison syndrome)
  - Viral infections (e.g., cytomegalovirus)
  - Vascular insufficiency (e.g., crack cocaine associated)
  - Radiation therapy
  - Chemotherapy (e.g., hepatic artery infusions)
  - Infiltrating disease (e.g., Crohn disease):
- Diseases and medical conditions associated with chronic peptic ulcer
  - Cirrhosis
  - Chronic renal failure
  - Chronic obstructive pulmonary disease
  - Cardiovascular disease
  - Organ transplantation

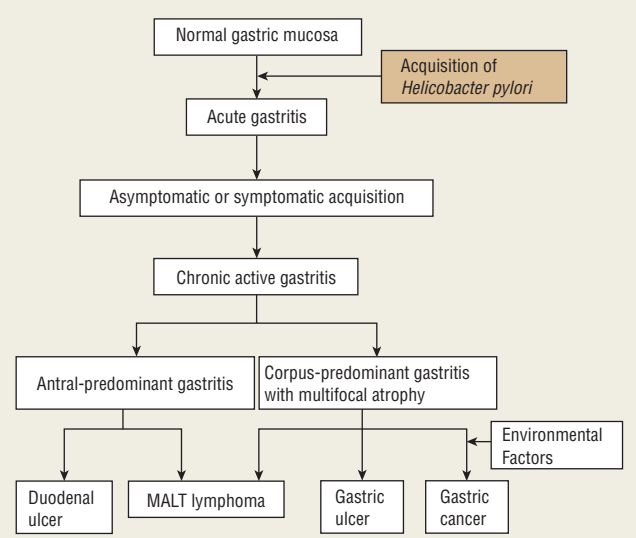

FIGURE 40-2. The natural history of *Helicobacter pylori* infection in the pathogenesis of gastric ulcer and duodenal ulcer, mucosa-associated lymphoid tissue (MALT) lymphoma, and gastric cancer.

The most common route of *H. pylori* transmission is person to person either by gastro–oral (vomitus) or fecal–oral (diarrhea) contact which occurs primarily during childhood.[2] Members of the same household are likely to become infected when someone in the same household is infected.[2] *H. pylori* can also be transmitted by the use of inadequately sterilized endoscopes.

NONSTEROIDAL ANTIINFLAMMATORY DRUGS

NSAIDs (Table 40–3) are widely used in the United States, particularly in individuals over 60 years of age, to treat chronic pain and inflammation.[1] These agents include prescription and nonprescription medications and low-dose aspirin used for cardiovascular and cerebrovascular risk reduction.[1,12–14] There is overwhelming evidence linking chronic NSAID (including aspirin) use to a variety of upper GI tract injuries.[1,12–16] NSAIDs cause superficial (topical) mucosal damage consisting of petechiae (intramucosal hemorrhages) within minutes of ingestion, and progress to erosions with continued use.[1] These lesions typically heal within a few days and rarely cause ulcers or acute upper GI bleeding. Gastroduodenal ulcers develop in about 25% of chronic NSAID users with continued use.[12] Gastric ulcers are most common, occur primarily in the antrum, and are of greater concern because of their potential to cause ulcer-related upper GI complications (see Table 40–1). As many as 2% to 4% of patients with an NSAID ulcer will bleed or perforate.[12] Each year, NSAIDs account for at least 100,000 hospitalizations and between 7,000 and 10,000 deaths in the United States.[12] NSAID-induced ulcers occur less frequently in the esophagus, small bowel, and colon.[16,17] How NSAIDs damage the lower GI tract is unclear, but the enteropathy is associated with lower GI bleeding.

TABLE 40-3 Selected Nonsteroidal Antiinflammatory Drugs (NSAIDs) and Cyclooxygenase-2 (COX-2) Inhibitors

- Nonsalicylates[a]
  - Nonselective (traditional) NSAIDs: indomethacin, piroxicam, ibuprofen, naproxen, sulindac, ketoprofen, ketorolac, flurbiprofen
  - Partially selective NSAIDs: etodolac, nabumetone, meloxicam, diclofenac, celocoxib
  - Selective COX-2 inhibitors: rofecoxib,[b] valdecoxib[b]
- Salicylates
  - Acetylated: aspirin
  - Nonacetylated: salsalate, trisalicylate

[a]Based on COX-1/COX-2 selectivity ratio.
[b]Withdrawn from U.S. market.

TABLE 40-4 Risk Factors Associated with Nonsteroidal Antiinflammatory Drug (NSAID)–Induced Ulcers and Upper Gastrointestinal Complications[a]

Age >65
Previous peptic ulcer
Previous ulcer-related upper GI complication
High-dose NSAIDs
Multiple NSAID use
Selection of NSAID (e.g., COX-1 vs COX-2 inhibition)
NSAID-related dyspepsia
Aspirin (including cardioprotective dosages)
Concomitant use of NSAID plus low-dose aspirin
Concomitant use of oral bisphosphonates (e.g., alendronate)
Concomitant use of corticosteroids
Concomitant use of anticoagulant or coagulopathy
Concomitant use of antiplatelet drugs (e.g., clopidogrel)
Concomitant use of selective serotonin reuptake inhibitor
Chronic debilitating disorders (e.g., cardiovascular disease, rheumatoid arthritis)
Helicobacter pylori infection
Cigarette smoking
Alcohol consumption

[a]Combinations of risk factors are additive.
Data from references 1, 12 to 15, 20, and 29.

Table 40–4 lists the risk factors associated with NSAID-induced ulcers and upper GI complications. Combinations of factors confer an additive risk.[12–16,18] Advanced age is an independent risk factor, and the incidence of NSAID-induced ulcers increases linearly with the age of the patient.[1] The high incidence of ulcer complications in older individuals may be explained by age-related changes in gastric mucosal defense. The relative risk of NSAID complications is increased for patients with a previous peptic ulcer and may be as high as 14-fold in those with a history of an ulcer-related complication.[1,16] The risk of adverse events is greatest during the first month after initiating continuous therapy and remains the same throughout treatment.[1]

NSAID ulcers and related complications are dose-dependent, but may occur with low doses of nonprescription NSAIDs and low cardioprotective dosages of aspirin (81 to 325 mg/day).[1,12–16] Factors such as NSAID potency, longer duration of effect, and a greater propensity to inhibit cyclooxygenase-1 (COX-1) versus COX-2 isoezymes are associated with increased risk (see Table 40–3).[1,16,18,19] NSAID-related dyspepsia, in itself, does not correlate directly with mucosal injury or clinical events. However, new-onset dyspepsia, changes in severity, or dyspepsia not relieved by antiulcer medications may suggest an ulcer or ulcer complication.[1] Nonacetylated salicylates (e.g., salsalate) may be associated with decreased GI toxicity.[1] Buffered or enteric-coated aspirin confers no added protection from upper GI events.[13]

NSAID ulcer and GI complication risk are increased with the use of multiple NSAIDs or the concomitant use of low-dose aspirin, oral bisphosphonates, corticosteroids, anticoagulants, antiplatelet drugs, and selective serotonin reuptake inhibitors.[1,12–16,20] The risk of an ulcer-related GI complication is greater when a NSAID or COX-2 inhibitor (see Table 40–3) is coadministered with low-dose aspirin than when either drug is taken alone.[1,13,16] The NSAID may also reduce the antiplatelet effects of aspirin, although NSAIDs vary in their effects on platelet function.[13–15] Corticosteroids, when used alone, do not potentiate the risk of ulcer or complications, but the relative risk is increased twofold in corticosteroid users who are

also taking concurrent NSAIDs.[1,16] The relative risk of GI bleeding increases up to 20-fold when NSAIDs are taken concomitantly with anticoagulants (e.g., warfarin) and up to sixfold with the concurrent use of serotonin reuptake inhibitors.[16,17] When clopidogrel is taken in combination with aspirin, an NSAID, or an anticoagulant, the risk of GI bleeding is increased compared with when these agents are taken alone.[13,15,16] Even when prescribed as monotherapy, clopidogrel increases the risk of rebleeding for patients with history of a bleeding ulcer.[13,15,16]

H. pylori and NSAIDs act independently to increase ulcer risk and ulcer-related bleeding and appear to have additive effects.[5,16] Thus, the incidence of peptic ulcer is higher in *H. pylori*–positive NSAID users. Whether *H. pylori* infection is actually a risk factor for NSAID ulcers remains controversial.[1,5,16] However, eradication is reported to reduce the incidence of peptic ulcer if undertaken prior to starting the NSAID but does not reduce the risk for patients who were previously taking an NSAID.[1,5,16]

CIGARETTE SMOKING

Epidemiologic evidence links cigarette smoking to PUD, but it is uncertain whether smoking causes peptic ulcers.[1] Ulcer risk is proportional to the number of cigarettes smoked and is modest when fewer than 10 cigarettes are smoked per day. Cigarette smoking impairs ulcer healing, promotes ulcer recurrence, and increases ulcer risk.[1] The exact mechanism by which cigarette smoking contributes to PUD remains unclear. Possible mechanisms include inhibition of pancreatic bicarbonate secretion and increases in gastric acid secretion, but these effects are inconsistent. Whether nicotine or other components of smoke are responsible for these physiologic alterations is unknown.

PSYCHOLOGICAL STRESS

The importance of psychological factors in the pathogenesis of PUD remains controversial.[1] Clinical observation suggests that ulcer patients are adversely affected by stressful life events. However, results from controlled trials are conflicting and have failed to document a cause-and-effect relationship.[1] Emotional stress may induce behavioral risks such as smoking and the use of NSAIDs or alter the inflammatory response or resistance to *H. pylori* infection. The role of stress and how it affects PUD is complex and probably multifactorial.

DIETARY FACTORS

The role of diet and nutrition in PUD is uncertain.[1] Coffee, tea, cola beverages, beer, milk, and spices may cause dyspepsia but do not increase the risk for PUD. Beverage restrictions and bland diets do not alter the frequency of ulcer recurrence. Although caffeine is a gastric acid stimulant, constituents in decaffeinated coffee or tea, caffeine-free carbonated beverages, beer, and wine may also increase gastric acid secretion. In high concentrations, alcohol ingestion is associated with acute gastric mucosal damage and upper GI bleeding; however, there is insufficient evidence to confirm that alcohol causes ulcers.[1]

PATHOPHYSIOLOGY

A physiologic imbalance between aggressive (gastric acid and pepsin) and protective factors (mucosal defense and repair) remain important issues in the pathophysiology of gastric and duodenal ulcers.[1,21] Gastric acid is secreted by the parietal cells, which contain receptors for histamine, gastrin, and acetylcholine.[21] Acid (as well as *H. pylori* infection and NSAID use) is an independent factor that contributes to the disruption of mucosal integrity.[1] Increased acid secretion has been observed for patients with duodenal ulcers and may be a consequence of *H. pylori* infection.[2,22] Patients with Zollinger-Ellison syndrome (ZES) (described in the section Zollinger-Ellison Syndrome) have profound gastric acid hypersecretion resulting from a gastrin-producing tumor.[3] In contrast, patients with gastric ulcer usually have normal or reduced rates of acid secretion (hypochlorhydria).

Acid secretion is expressed as the amount of acid secreted under basal or fasting conditions, basal acid output (BAO); after maximal stimulation, maximal acid output (MAO); or in response to a meal.[21] Basal, maximal, and meal-stimulated acid secretion varies according to time of day and the individual's psychological state, age, gender, and health status. The BAO follows a circadian rhythm, with the highest acid secretion occurring at night and the lowest in the morning. An increase in the BAO:MAO ratio suggests a basal hypersecretory state such as ZES. A review of gastric acid secretion, and its regulation can be found elsewhere.[21]

Pepsin is an important cofactor that plays a role in the proteolytic activity involved in ulcer formation.[21] Pepsinogen, the inactive precursor of pepsin, is secreted by the chief cells located in the gastric fundus (see Fig. 40–1). Pepsin is activated by acid pH (optimal pH of 1.8 to 3.5), inactivated reversibly at pH 4, and irreversibly destroyed at pH 7.

Mucosal defense and repair mechanisms (mucus and bicarbonate secretion, intrinsic epithelial cell defense, and mucosal blood flow) protect the gastroduodenal mucosa from noxious endogenous and exogenous substances.[1,21] The viscous nature and near-neutral pH of the mucus-bicarbonate barrier protect the stomach from the acidic contents in the gastric lumen. Mucosal repair after injury is related to epithelial cell restitution, growth, and regeneration. The maintenance of mucosal integrity and repair is mediated by the production of endogenous prostaglandins. The term *cytoprotection* is often used to describe this process, but *mucosal defense* and *mucosal protection* are more accurate terms, as prostaglandins prevent deep mucosal injury and not superficial damage to individual cells. Gastric hyperemia and increased prostaglandin synthesis characterize adaptive cytoprotection, the short-term adaptation of mucosal cells to mild topical irritants. This phenomenon enables the stomach to initially withstand the damaging effects of irritants. Alterations in mucosal defense that are induced by *H. pylori* or NSAIDs are the most important cofactors in the formation of peptic ulcers.

HELICOBACTER PYLORI

H. pylori is a spiral-shaped, pH-sensitive, gram-negative, microaerophilic bacterium that resides between the mucus layer and surface epithelial cells in the stomach, or any location where gastric-type epithelium is found.[2,22] The combination of its spiral shape and flagellum permits it to move from the lumen of the stomach, where the pH is low, to the mucus layer, where the local pH is neutral. *H. pylori* produces large amounts of urease, which hydrolyzes urea in the gastric juice and converts it to ammonia and carbon dioxide.[2] The local buffering effect of ammonia creates a neutral microenvironment within and surrounding the bacterium, which protects it from the lethal effect of gastric acid. *H. pylori* also produces acid-inhibitory proteins, which allows it to adapt to the low-pH environment of the stomach.[2]

H. pylori binds to specific regions within the stomach. It attaches to gastric-type epithelium by adherence pedestals, which prevent the organism from being shed during cell turnover and mucus secretion.[2] Colonization of the antrum and corpus (body) of the stomach is associated with gastric ulcer and cancer.[1,2,22] Antral organisms colonize gastric metaplastic tissue (gastric tissue that develops in the duodenum secondary to changes in gastric acid or bicarbonate secretion) leading to duodenal ulcer (see Fig. 40–2).[1,2] Although *H. pylori* causes chronic gastric mucosal inflammation in all infected

individuals, only a minority actually develop an ulcer or gastric cancer.[1,2,8] The difference in the diverse clinical outcomes is related to variations in bacterial pathogenicity and host susceptability.[2,22]

Mucosal injury is produced by (1) elaborating bacterial enzymes (urease, lipases, and proteases), (2) adherence, and (3) *H. pylori* virulence factors.[2,22] Lipases and proteases degrade gastric mucus, ammonia produced by urease may be toxic to gastric epithelial cells, and bacterial adherence enhances the uptake of toxins into gastric epithelial cells. *H. pylori* induces gastric inflammation by altering the host inflammatory response and damaging epithelial cells directly by cell-mediated immune mechanisms or indirectly by activated neutrophils or macrophages attempting to phagocytose bacteria or bacterial products.[2,22] However, *H. pylori* strains are genetically diverse and account for differences in adaptation within the human host. Two of the most important are cytotoxin-associated gene protein (CagA) and vacuolating cytotoxin (VacA). About 60% of *H. pylori* strains in the United States possess CagA, but CagA-positive strains increase the risk for severe PUD, gastritis, and gastric cancer compared with CagA-negative strains.[2,22] The VacA gene codes for the Vac-A cytotoxin, a vacuolizating toxin. Although VacA is present in most all *H pylori* strains, strains vary in cytotoxicity and increased risk for peptic ulcer and gastric cancer.[2,22] Host polymorphisms are important markers of disease susceptibility and may identify high-risk patients.[2,22] Polymorphisms of interleukin (IL)-1β and its receptor antagonist, as well as tumor necrosis factor α (TNF-α) and IL-10, may be associated with increased gastric acid secretion and duodenal ulcer or acid suppression and gastric cancer.[2,22]

NONSTEROIDAL ANTIINFLAMMATORY DRUGS

NSAIDs, including aspirin (see Table 40–3), cause gastric mucosal damage by two important mechanisms: (1) direct or topical irritation of the gastric epithelium and (2) systemic inhibition of endogenous mucosal prostaglandin synthesis.[1,13] Although the initial injury is initiated topically by the acidic properties of many of the NSAIDs, systemic inhibition of the protective prostaglandins limits the ability of the mucosa to defend itself against injury and thus plays the predominant role in the development of gastric ulcer.[1,13]

Topical irritant properties are predominantly associated with acidic NSAIDs (e.g., aspirin) and their ability to decrease the hydrophobicity of the mucous gel layer in the gastric mucosa. Most nonaspirin NSAIDs have topical irritant effects, but aspirin is the most damaging. Although NSAID prodrugs, enteric-coated aspirin tablets, salicylate derivatives, and parenteral or rectal preparations are associated with less-acute topical gastric mucosal injury, they can cause ulcers and related GI complications as a result of their systemic inhibition of endogenous PGs.[1]

Cyclooxygenase (COX) is the rate-limiting enzyme in the conversion of arachidonic acid to prostaglandins and is inhibited by NSAIDs (Fig. 40–3). Two similar COX isoforms have been identified: cyclooxygenase-1 (COX-1) is found in most body tissue, including the stomach, kidney, intestine, and platelets; cyclooxygenase-2 (COX-2) is undetectable in most tissues under normal physiologic conditions, but its expression can be induced during acute inflammation and arthritis (Fig. 40–4).[1,13] COX-1 produces protective prostaglandins that regulate physiologic processes such as GI mucosal integrity, platelet homeostasis, and renal function. COX-2 is induced (unregulated) by inflammatory stimuli such as cytokines and produces prostaglandins involved with inflammation, fever, and pain. COX-2 is also constitutionally expressed in organs such as the brain, kidney, and reproductive tract. Adverse effects (e.g., GI or renal toxicity) of NSAIDs are primarily associated with the inhibition of COX-1, whereas antiinflammatory actions result primarily from NSAID inhibition of COX-2.[1,13]

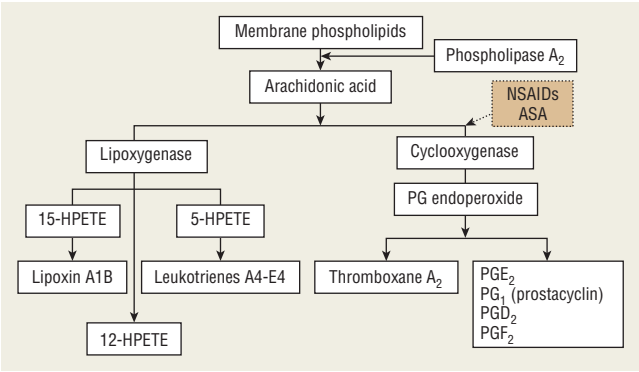

FIGURE 40-3. Metabolism of arachidonic acid after its release from membrane phospholipids. *Broken arrow* indicates inhibitory effects. (ASA, aspirin; HPETE, hydroperoxyeicosatetraenoic acid; NSAIDs, nonsteroidal antiinflammatory drugs; PG, prostaglandin.)

The COX-1-to-COX-2 inhibitory ratio determines the relative GI toxicity of a specific NSAID. Nonselective NSAIDs, including aspirin (see Table 40–3), inhibit both COX-1 and COX-2 to varying degrees and are associated with an increased propensity to cause gastric ulcers.[1,13] In contrast, the selective COX-2 inhibitors are associated with a reduction in ulcers and related GI complications, but the benefit of celecoxib, is less that that of rofecoxib and valdecoxib (see Table 40–3). The addition of aspirin to a selective COX-2 inhibitor reduces its ulcer-sparing benefit and increases ulcer risk.[1,13] Aspirin and nonaspirin NSAIDs irreversibly inhibit platelet COX-1, resulting in decreased platelet aggregation and prolonged bleeding times, thereby increasing the potential for upper and lower GI bleeding.[1,13,15] Coadministration of selected NSAIDs may reduce the antiplatelet effects of aspirin.[13–15] Clopidogrel and other medications that impair angiogenesis do not cause ulcers, per se, but may impair healing of gastric erosions leading to ulceration.[13,15]

COMPLICATIONS

Upper GI bleeding, perforation, and obstruction occur with *H. pylori*–associated and NSAID-induced ulcers and constitute the most serious, life-threatening complication of chronic PUD.[1,23] Bleeding is caused by the erosion of an ulcer into an artery. It may be occult (hidden) and insidious or may present as melena

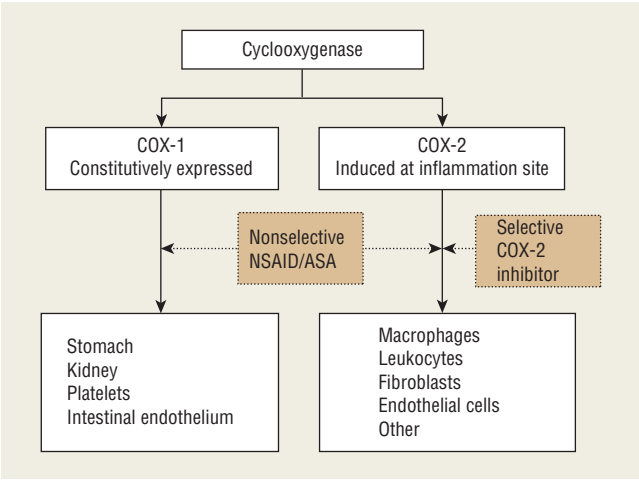

FIGURE 40-4. Tissue distribution and actions of cyclooxygenase (COX) isoenzymes. Nonselective nonsteroidal antiinflammatory drugs (NSAIDs) including aspirin (ASA) inhibit COX-1 and COX-2 to varying degrees; COX-2 inhibitors inhibit only COX-2. *Broken arrow* indicates inhibitory effects.

(black-colored stools) or hematemesis (vomiting of blood). The use of NSAIDs (especially in older adults) is the most important risk factor for upper GI bleeding. Deaths occur primarily in patients who continue to bleed or in those patients who rebleed after the initial bleeding has stopped (see Upper Gastrointestinal Bleeding).

Ulcer-related perforation into the peritoneal cavity is generally considered a surgical emergency.[1,23] About one third to one half of perforated ulcers are associated with the use of NSAIDs, with the highest mortality reported in the elderly.[23] The pain of perforation is usually sudden, sharp, and severe, beginning first in the epigastrium, but quickly spreading over the entire abdomen. Most patients experience ulcer symptoms prior to perforation. However, older patients who experience perforation in association with NSAID use may be asymptomatic. Penetration occurs when an ulcer burrows into an adjacent structure (pancreas, biliary tract, or liver) rather than opening freely into a cavity.

Gastric outlet obstruction is related to mechanical obstruction caused by scarring, muscular spasm or edema of the duodenal bulb usually resulting from chronic ulcercation.[1,23] Symptoms occur over several months and include early satiety, bloating, anorexia, nausea, vomiting, and weight loss. Perforation, penetration, and gastric outlet obstruction occur most often with long-standing PUD.

Treatment of PUD has improved so that even the most virulent ulcers can be managed with medication. Intractability to drug therapy is an infrequent manifestation of PUD and an infrequent indication for surgery.

SIGNS AND SYMPTOMS

The clinical presentation of PUD varies depending on the severity of epigastric pain and the presence of complications (Table 40–5).[1] Ulcer-related pain in duodenal ulcer often occurs 1 to 3 hours after meals and is usually relieved by food, but this is variable. In gastric ulcer, food may precipitate or accentuate ulcer pain. Antacids usually provide immediate pain relief in most ulcer patients. Pain usually diminishes or disappears during treatment; however, recurrence of epigastric pain after healing often suggests an unhealed or recurrent ulcer.

The presence or absence of epigastric pain does not define an ulcer.[1] Ulcer healing does not necessarily render the patient asymptomatic. Why symptoms remain is unclear, but it may relate to sensitization of afferent nerves in response to mucosal injury.[1] Conversely, the absence of pain does not preclude an ulcer diagnosis especially in the elderly who may present with a "silent" ulcer complication. The reasons for this are unclear, but may relate to differences in the way the elderly perceive pain or the analgesic effect of NSAIDs.

Dyspepsia in itself is of little clinical value when assessing subsets of patients who are most likely to have an ulcer. Patients taking NSAIDs often report dyspepsia, but dyspeptic symptoms do not directly correlate with an ulcer. Individuals with dyspeptic symptoms may have either uninvestigated (no upper endoscopy) or investigated (underwent upper endoscopy) dyspepsia. If an ulcer is not confirmed in a patient with ulcer-like symptoms at the time of endoscopy, the disorder is referred to as *nonulcer dyspepsia*.[9] Ulcer-like symptoms may occur in the absence of peptic ulceration in association with *H. pylori* gastritis or duodenitis. There is no one sign or symptom that differentiates between *H. pylori*–positive and NSAID-induced ulcer.

DIAGNOSIS

Routine laboratory tests are not helpful in establishing the diagnosis of PUD (see Table 40–5).[1]

TABLE 40-5 Clinical Presentation of Peptic Ulcer Disease

General
- Mild epigastric pain or acute life-threatening upper gastrointestinal complications

Symptoms
- Abdominal pain that is often epigastric and described as burning but may present as vague discomfort, abdominal fullness, or cramping
- A typical nocturnal pain that awakens the patient from sleep (especially between 12 AM and 3 AM)
- The severity of ulcer pain varies from patient to patient and may be seasonal, occurring more frequently in the spring or fall; episodes of discomfort usually occur in clusters, lasting up to a few weeks and followed by a pain-free period or remission lasting from weeks to years
- Changes in the character of the pain may suggest the presence of complications
- Heartburn, belching, and bloating often accompany the pain
- Nausea, vomiting, and anorexia are more common for patients with gastric ulcer than with duodenal ulcer but may also be signs of an ulcer-related complication

Signs
- Weight loss associated with nausea, vomiting, and anorexia
- Complications including ulcer bleeding, perforation, penetration, or obstruction

Laboratory tests
- Gastric acid secretory studies
- The hematocrit and hemoglobin are low with bleeding, and stool hemoccult tests are positive.
- Tests for *Helicobacter pylori* (see Table 40–6).

Diagnostic tests
- Fiberoptic upper endoscopy (esophagogastroduodenoscopy) detects more than 90% of peptic ulcers and permits direct inspection, biopsy, visualization of superficial erosions, and sites of active bleeding.
- Upper gastrointestinal radiography with barium has been replaced with upper endoscopy as the diagnostic procedure of choice for supsected peptic ulcer.

TESTS FOR *HELICOBACTER PYLORI*

The diagnosis of *H. pylori* infection can be made using endoscopic or nonendoscopic tests (Table 40–6).[2,5,24] The tests that require upper endoscopy are invasive, more expensive, and usually require a mucosal biopsy for histology, culture, or detection of urease activity. At least three tissue samples are taken from specific areas of the stomach, as patchy distribution of *H. pylori* infection can lead to false-negative results. Because certain medications may decrease the sensitivity of rapid urease test, antibiotics and bismuth salts should be withheld for 4 weeks and proton pump inhibitors (PPIs) for 1 to 2 weeks prior to endoscopic testing.[2,5] If the patient has been taking these medications, then a gastric biopsy for histology should be performed.[5]

Two types of nonendoscopic tests are available: tests that identify active infection and tests that detect antibodies (see Table 40–6). Antibody tests do not differentiate between active infection and previously eradicated *H. pylori*. The nonendoscopic tests include the urea breath test (UBT), serologic antibody detection tests, and the fecal antigen test. These tests are less invasive, more convenient, and less expensive than the endoscopic tests.[2,5,24]

The UBT is the most accurate noninvasive test and is based on *H. pylori* urease activity.[5] The ^{13}carbon (nonradioactive isotope) and ^{14}carbon (radioactive isotope) tests require that the patient ingest radiolabeled urea, which is then hydrolyzed by *H. pylori* (if present in the stomach) to ammonia and radiolabeled bicarbonate. The radiolabeled bicarbonate is absorbed in the blood and excreted in the breath. A mass spectrometer is used to detect ^{13}Carbon whereas ^{14}Carbon is measured using a scintillation counter. The fecal antigen test is less expensive and easier to perform than the UBT, and may

TABLE 40-6 Tests for Detection of Helicobacter pylori

Test	Description	Comments
Endoscopic tests		
Histology	Microbiologic examination using various stains	Gold standard; >95% sensitive and specific; permits classification of gastritis; results are not immediate; not recommended for initial diagnosis; tests for active *H. pylori* infection
Culture	Culture of biopsy	Enables sensitivity testing to determine appropriate treatment or antibiotic resistance; 100% specific; results are not immediate; not recommended for initial diagnosis; used after failure of second-line treatment; tests for active *H. pylori* infection
Biopsy (rapid) urease	*H. pylori* urease generates ammonia, which causes a color change	Test of choice at endoscopy; >90% sensitive and specific; easily performed; rapid results (usually within 24 hours); tests for active *H. pylori* infection
Polymerase chain reaction	*H. pylori* DNA detected gastric tissue	Test is highly specific and sensitive; high rate of false positives and false negatives; positive DNA does not directly equate top presence of the organism; considered a research technique
Nonendoscopic tests		
Antibody detection (laboratory based)	Detects antibodies to *H. pylori* in serum using laboratory-based enzyme-linked immunosorbent assay (ELISA) tests and latex agglutination techniques	Quantitative; less sensitive and specific than endoscopic tests; more accurate than in office; unable to determine if antibody is related to active or cured infection; antibody titers vary markedly among individuals and take 6 months to 1 year to return to the uninfected range; not affected by PPIs or bismuth; antibiotics given for unrelated indications may cure the infection, but antibody test will remain positive
Antibody detection (can be performed in office or near patient)	Detects IgG antibodies to *H. pylori* in whole blood or finger stick	Qualitative; quick (within 15 minutes); unable to determine if antibody is related to active or cured infection; most patients remain seropositive for at least 6 months to 1 year after *H. pylori* eradication; not affected by PPIs, bismuth, or antibiotics
Urea breath test	*H. pylori* urease breaks down ingested labeled C-urea, patient exhales labeled CO_2	Tests for active *H. pylori* infection; 95% sensitive and specific; results take about 2 days; antibiotics, bismuth, PPIs, and H_2RAs may cause false-negative results; withhold PPIs or H_2RAs (1–2 weeks) and bismuth or antibiotics (4 weeks) prior to testing; recommended test to confirm posttreatment eradication of *H. pylori*
Fecal antigen	Identifies *H. pylori* antigen in stool by enzyme immunoassay using polyclonal anti-*H. pylori* antibody	Tests for active *H. pylori* infection; sensitivity and specificity comparable to urea breath test when used for initial diagnosis; antibiotics, bismuth, and PPIs may cause false-negative results, but to a lesser extent than with the urea breath test; may be used posttreatment to confirm eradication, but patients may have a reluctance to obtain stool samples

H_2RA, H_2-receptor antagonist; PPI, proton pump inhibitor.
Data from references 2, 5, and 25.

be useful in children. Although comparable to the UBT in the initial detection of *H. pylori*, the fecal antigen test is less accurate when used to confirm *H. pylori* eradication posttreatment and is considered an alternative to the UBT.

Serologic tests are a cost-effective alternative for the initial diagnosis of *H. pylori* infection in the untreated patient.[2,5] Antibodies to *H. pylori* usually develop about 3 weeks after infection and remain present after successful eradication.[5] Therefore, serology should not be used to confirm *H. pylori* eradication.[2,5] Office-based tests are less expensive, widely available and provide rapid results, but the results are less accurate and more variable than the laboratory-based tests. Salivary and urine antibody tests are under investigation.[2]

Testing for *H. pylori* is only recommended if eradication is planned. Serologic antibody testing is a reasonable choice if endoscopy is not planned. The diagnostic accuracy of *H. pylori* tests for patients with an active bleeding ulcer has been questioned because of the potential for false-negative results. However, endoscopic biopsy-based tests such as the rapid urease test have a high degree of specificity in these patients (see Peptic Ulcer-Related Bleeding).[5]

Confirmation of eradication is indicated posttreatment of active ulcers, previous ulcers, MALT lymphoma, endoscopic resection of gastric cancer, and uninvestigated dyspepsia, but routine testing for all patients is neither cost-effective nor practical.[5] The decision to test posttreatment should be patient specific and take into consideration the patient's diagnosis, age, and ulcer history. The UBT is the preferred nonendoscopic test to confirm *H. pylori* eradication but must be delayed at least 4 weeks after the completion of treatment to avoid confusing bacterial suppression with eradication. The term *eradication* or *cure* is used when posttreatment tests conducted 4 weeks after the end of treatment do not detect the organism. Quantitative antibody tests are impractical for posttreatment as antibody titers remain elevated for long periods of time. A negative posttreatment antibody test, however, is considered reliable.

IMAGING AND ENDOSCOPY

The diagnosis of PUD depends on visualizing the ulcer crater either by upper GI radiography or upper endoscopy (see Table 40–5).[1] In the past, radiograpy was the initial diagnostic procedure of choice because of its lower cost, greater availability, and greater safety. Today, upper endoscopy has replaced radiography because it provides a more accurate diagnosis and permits direct visualization of the ulcer.

CLINICAL COURSE AND PROGNOSIS

The natural history of PUD is characterized by periods of exacerbations and remissions.[1] Ulcer pain is usually recognizable and episodic, but symptoms are variable, especially in older adults and for patients taking NSAIDs. Antiulcer medications, including the histamine-2 receptor antagonists (H_2RAs), PPIs, and sucralfate, relieve symptoms, accelerate ulcer healing, and reduce the risk of ulcer recurrence, but they do not cure the disease. Both duodenal and gastric ulcers recur unless the underlying cause (*H. pylori* or NSAID) is removed. Successful *H. pylori* eradication markedly decreases ulcer recurrence and complications. Prophylactic cotherapy or a COX-2 inhibitor decreases the risk of upper GI events for patients who are taking NSAIDs. GI bleeding, perforation, or obstruction remain troublesome complications of chronic PUD. Mortality for patients with gastric ulcer is slightly higher than in duodenal ulcer and the general population. The development of gastric cancer in *H. pylori*–infected individuals is a slow process that occurs over 20 to 40 years and is associated with a lifetime risk of less than 1%.[2,8]

TREATMENT

DESIRED OUTCOME

The treatment of chronic PUD varies depending on the etiology of the ulcer (*H. pylori* or NSAID), whether the ulcer is initial or recurrent, and whether complications have occurred (Fig. 40–5). Overall treatment is aimed at relieving ulcer pain, healing the ulcer, preventing ulcer recurrence, and reducing ulcer-related complications. The goal of therapy for *H. pylori*–positive patients with an active ulcer, a previously documented ulcer, or a history of an ulcer-related complication, is to eradicate *H. pylori*, heal the ulcer, and cure the disease. Successful eradication heals ulcers and reduces the risk of recurrence for most patients. The goal of therapy for a patient with a NSAID-induced ulcer is to heal the ulcer as rapidly as possible. Patients who are at high risk of developing NSAID ulcers should receive prophylactic cotherapy or be switched to a selective COX-2 inhibitor NSAID (if available) to reduce ulcer risk and related complications. When possible, the most cost-effective drug regimen should be used.

GENERAL APPROACH TO TREATMENT

The eradication of *H. pylori* infection with antimicrobials such as clarithromycin, metronidazole, amoxicillin, bismuth salts, and antisecretory drugs (PPIs or H_2RAs) relieve ulcer symptoms, heal the ulcer, and eradicate *H. pylori* infection. PPIs are preferred to H_2RAs or sucralfate for healing *H. pylori*–negative NSAID-induced ulcers because they accelerate ulcer healing and provide more effective relief of symptoms. Treatment with a PPI should be extended to 8 to 12 weeks if the NSAID must be continued. A PPI-based *H. pylori* eradication regimen is recommended when the patient with an active ulcer is taking an NSAID and is *H. pylori*–positive. Prophylactic cotherapy with either a PPI or misoprostol decreases ulcer risk and upper GI complications for patients taking nonselective NSAIDs. Selective COX-2 inhibitor NSAIDs (if available) may be used as an alternative to a nonselective NSAID, but their beneficial GI effect when taken with low-dose aspirin is negated and their association with adverse cardiovascular effects reduce their usefulness.

Dietary modifications are important for patients who are unable to tolerate certain foods and beverages. Lifestyle modifications such as

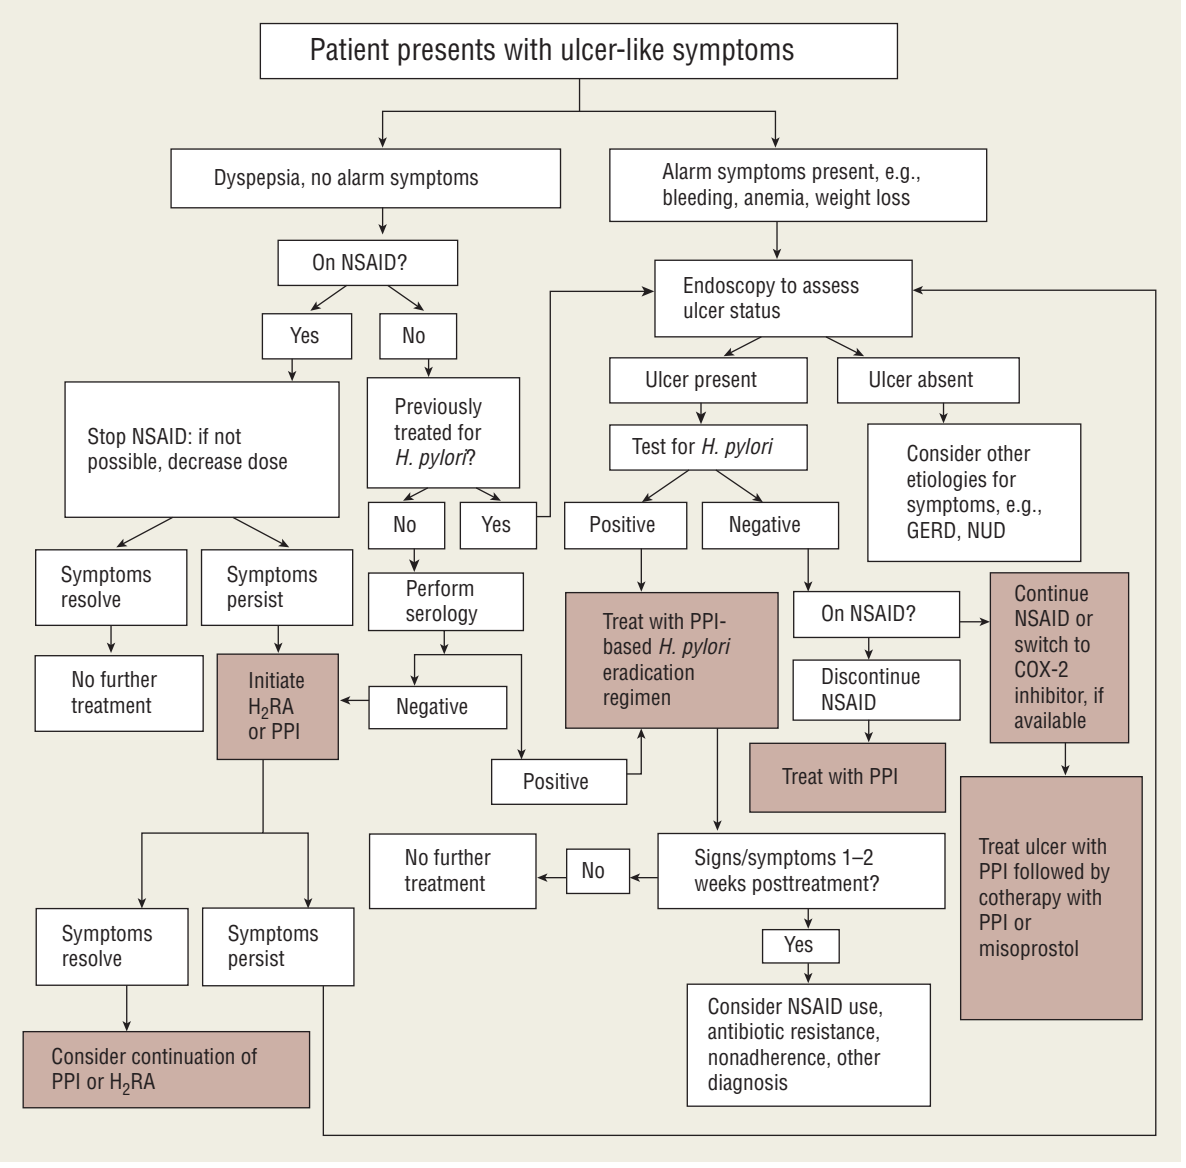

FIGURE 40-5. Algorithm. Guidelines for the evaluation and management of a patient who presents with dyspeptic or ulcer-like symptoms. (COX-2, cyclooxygenase-2; GERD, gastroesophageal reflux disease; *H. pylori*, *Helicobacter pylori*; H_2RA, H_2-receptor antagonist; PPI, proton pump inhibitor; NSAID, nonsteroidal antiinflammatory drug; NUD, nonulcer dyspepsia.)

reducing stress and stopping cigarette smoking is encouraged. Surgery may be necessary for patients with ulcer-related complications.

NONPHARMACOLOGIC THERAPY

1 Patients with PUD should eliminate or reduce psychological stress, cigarette smoking, and the use of NSAIDs (including aspirin). Although there is no "antiulcer diet," the patient should avoid foods and beverages (e.g., spicy foods, caffeine, and alcohol) that cause dyspepsia or that exacerbate ulcer symptoms. If possible, alternative agents such as acetaminophen or nonacetylated salicylate (e.g., salsalate) should be used for relief of pain. Elective surgery for PUD is rarely performed today because of highly effective medical management. A subset of patients, however, may require emergency surgery for bleeding, perforation, or obstruction. In the past, surgical procedures were performed for medical treatment failures and included vagotomy with pyloroplasty or vagotomy with antrectomy.[23] Vagotomy (truncal, selective, or parietal cell) inhibits vagal stimulation of gastric acid. A truncal or selective vagotomy frequently results in postoperative gastric dysfunction and requires a pyloroplasty or antrectomy to facilitate gastric drainage. When an antrectomy is performed, the remaining stomach is anastomosed with the duodenum (Billroth I) or with the jejunum (Billroth II). A vagotomy is unnecessary when an antrectomy is performed for gastric ulcer. Postoperative consequences include postvagotomy diarrhea, dumping syndrome, anemia, and recurrent ulceration.

PHARMACOLOGIC THERAPY

Recommendations

2 Table 40–7 presents guidelines for the eradication of infection in *H. pylori*–positive individuals. Table 40–8 lists regimens used to eradicate *H. pylori* infection.

3 First-line therapy is usually initiated with a PPI-based three-drug regimen for 10 to 14 days. If a second course of treatment is required, the PPI-based three-drug regimen should contain different antibiotics or a four-drug regimen with a bismuth salt, metronidazole, tetracycline, and a PPI should be used.

TABLE 40-7 Guidelines for the Eradication of *Helicobacter pylori* Infection

Indications for treatment of *H. pylori* infection

- Established indications for the treatment of *H. pylori* include gastric or duodenal ulcer, mucosa-associated lymphoid tissue (MALT) lymphoma, after endoscopic resection of gastric cancer, and uninvestigated dyspepsia
- Controversial indications for the treatment of *H. pylori* infection include nonulcer dyspepsia, gastroesophageal reflux disease, individuals taking nonsteroidal antiinflammatory drugs (NSAIDs), individuals at high risk for gastric cancer, and unexplained iron deficiency anemia.

Initial treatment of *H. pylori* infection

- Use only those eradication regimens that are of proven effectiveness in the United States
- In the United States, first-line treatment should include a proton pump inhibitor (PPI), clarithromycin, and either amoxicillin or metronidazole (PPI-based triple therapy) for 10–14 days
- The PPI-based triple therapy amoxicillin-containing regimen is preferred initially because bacterial resistance to amoxicillin is almost absent, it has fewer adverse effects, and it leaves metronidazole as a backup agent for second-line therapy
- In penicillin allergic patients, metronidazole should be substituted for amoxicillin in the PPI- based triple therapy regimen and yields similar results when combined with clarithromycin
- An alternate initial strategy includes a PPI or H_2RA, bismuth salt, tetracycline, and metronidazole (bismuth-based quadruple therapy) for 10–14 days.
- Sequential therapy consisting of a PPI and amoxicillin for 5 days followed by a PPI, clarithromycin, and metronidazole for 5 days is an alternative to PPI-based triple therapy or PPI-based quadruple therapy, but requires further validation before it can be recommended as first-line therapy in the United States.

Eradication of *H. pylori* after initial treatment failure

- Avoid antibiotics that have been used in previous eradication regimens.
- Bismuth-based quadruple therapy with a bismuth salt, tetracycline, metronidazole, and a PPI or H_2RA for 10–14 days is an acceptable treatment regimen for persistent *H. pylori* infections.
- PPI-based triple therapy with levofloxacin and amoxicillin for 10 days may be more effective and better tolerated than PPI-based quadruple therapy with a bismuth salt, tetracycline, and metronidazole, but it requires further validation in the United States.

Data from references 5, 25 to 29.

TABLE 40-8 Drug Regimens Used to Eradicate *Helicobacter pylori*

Drug #1	Drug #2	Drug #3	Drug #4
Proton pump inhibitor–based triple therapy[a]			
PPI once or twice daily[b]	Clarithromycin 500 mg twice daily	Amoxicillin 1 g twice daily *or* metronidazole 500 mg twice daily	
Bismuth-based quadruple therapy[a]			
PPI or H_2RA once or twice daily[b,c]	Bismuth subsalicylate[d] 525 mg 4 times daily	Metronidazole 250–500 mg 4 times daily	Tetracycline 500 mg 4 times daily
Sequential therapy[e]			
PPI once or twice daily on days 1–10[b]	Amoxicillin 1 g twice daily on days 1–5	Metronidazole 250–500 mg twice daily on days 6–10	Clarithromycin 250–500 mg twice daily on days 6–10
Second-line (salvage) therapy for persistent infections			
PPI or H_2RA once or twice daily[b,c]	Bismuth subsalicylate[d] 525 mg 4 times daily	Metronidazole 250–500 mg 4 times daily	Tetracycline 500 mg 4 times daily
PPI once or twice daily[b,f]	Amoxicillin 1 g twice daily	Levofloxacin 250 mg twice daily	

H_2RA, H_2-receptor antagonist; PPI, proton pump inhibitor.

[a]Although treatment is minimally effective if used for 7 days, 10–14 days is recommended. The antisecretory drug may be continued beyond antimicrobial treatment for patients with a history of a complicated ulcer, e.g., bleeding, or in heavy smokers.

[b]Standard PPI peptic ulcer healing dosages given once or twice daily (see Table 40–9).

[c]Standard H_2RA peptic ulcer healing dosages may be used in place of a PPI (see Table 40–9).

[d]Bismuth subcitrate potassium (biskalcitrate) 140 mg, as the bismuth salt, is contained in a prepackaged capsule (Pylera), along with metronidazole 125 mg and tetracycline 125 mg; three capsules are taken with each meal and at bedtime; a standard PPI dosage is added to the regimen and taken twice daily. All medications are taken for 10 days.

[e]Requires validation as first-line therapy in the United States.

[f]Requires validation as rescue therapy in the United States.

Data from references 5, 25 to 29.

TABLE 40-9 Oral Drug Regimens Used to Heal Peptic Ulcers and Maintain Ulcer Healing

Generic Name	Prescription Brand Name	Duodenal or Gastric Ulcer Healing (mg/dose)	Maintenance of Ulcer Healing (mg/dose)
Proton pump inhibitors			
Omeprazole	Prilosec, various	20–40 daily	20–40 daily
Omeprazole sodium bicarbonate	Zegerid	20–40 daily	20–40 daily
Lansoprazole	Prevacid, various	15–30 daily	15–30 daily
Rabeprazole	Aciphex	20 daily	20 daily
Pantoprazole	Pantoprazole, various	40 daily	40 daily
Esomeprazole	Nexium	20–40 daily	20–40 daily
Dexlansoprazole	Dexilant	30–60 daily	30 daily
H_2-receptor antagonists			
Cimetidine	Tagamet, various	300 four times daily 400 twice daily 800 at bedtime	400–800 at bedtime
Famotidine	Pepcid, various	20 twice daily 40 at bedtime	20–40 at bedtime
Nizatidine	Axid, various	150 twice daily 300 at bedtime	150–300 at bedtime
Ranitidine	Zantac, various	150 twice daily 300 at bedtime	150–300 at bedtime
Promote mucosal defense			
Sucralfate	Carafate, various	1 g 4 times daily 2 g twice daily	1–2 g twice daily 1 g 4 times daily

Patients with NSAID-induced ulcers should be tested to determine their *H. pylori* status. If *H. pylori*–positive, treatment should be initiated with a PPI-based three-drug regimen. If *H. pylori*–negative, the NSAID should be discontinued, and the patient treated with either a PPI, H_2RA, or sucralfate (see Table 40–9). If the NSAID is continued, treatment should be initiated with a PPI (if *H. pylori* negative) or with a PPI-based three-drug regimen (if *H. pylori* positive). Cotherapy with a PPI or misoprostol or switching to a selective COX-2 inhibitor (if available) is recommended for patients at risk of developing an ulcer-related complication (see Table 40–10).

Maintenance therapy with a PPI or H_2RA should be limited to high-risk patients with ulcer complications, patients who fail eradication, and those with *H. pylori*–negative ulcers. Treatment failure is associated with poor medication adherence, antimicrobial resistance, NSAID use, cigarette smoking, acid hypersecretion, or tolerance to the antisecretory effects of an H_2RA.

Treatment of *Helicobacter Pylori*–Positive Ulcers

This chapter focuses on the eradication of *H. pylori* in adults.[25–29] A discussion of the treatment of *H. pylori* infection in children is found elsewhere.[30,31]

The treatment of *H. pylori*–positive PUD should be effective, well tolerated, easy to adhere to, and cost-effective. Historically, none of these factors have been addressed in a systematic way making it difficult to identify the best evidence-based treatment regimens.[1] Successful eradication depends on the drug regimen, resistance to the antibiotics used, duration of therapy, medication adherence, and genetic polymorphism.[25–29] *H. pylori* regimens should have eradication (cure) rates of at least 80% based on intention-to-treat analysis or at least 90% based on per-protocol analysis, and they should minimize the potential for antimicrobial resistance.[1,25,29] Not one antibiotic, bismuth salt, or antiulcer drug achieves this goal, but clarithromycin is the single most effective antibiotic. Two-drug regimens that combine a PPI and either amoxicillin or clarithromycin have yielded marginal and variable eradication rates in the United States and are not recommended.[1,5] In addition, the use of only one antibiotic is associated with a higher rate of antimicrobial resistance.

Drug regimens (see Table 40–8) that combine an antisecretory drug with two antibiotics (triple therapy) or with two antibiotics and a bismuth salt (quadruple therapy) usually increase eradication rates to acceptable levels and reduce the risk of antimicrobial resistance.[5,25–29] When selecting an initial eradication regimen, an antibiotic combination should be used that permits second-line treatment (if necessary) with different antibiotics. The antibiotics that have been most extensively studied and found to be effective in various combinations include clarithromycin, amoxicillin, metronidazole, and tetracycline.[1] Because of insufficient data, ampicillin should not be substituted for amoxicillin, doxycycline should not be substituted for tetracycline,

TABLE 40-10 Guidelines for Reducing Gastrointestinal Risk for Patients Receiving Chronic NSAID Therapy

Gastrointestinal risk factors (see Table 40–4)

Cardiovascular Risk	No or Low GI Risk (No risk factors)	Moderate GI Risk (1–2 risk factors)	High GI Risk (>2 risk factors or prior ulcer or ulcer-related complication)
	Age < 65 years)	Age ≥ 65 years High-dose NSAIDs Concomitant use of aspirin, corticosteroids, or anticoagulants	Age ≥ 65 years Concomitant use of aspirin corticosteroids, or anticoagulants Dual antiplatelet therapy
No or low CV risk (patient does not require low-dose aspirin)	Nonselective NSAID or partially selective NSAID (see Table 40–3)	Nonselective NSAID or partially selective NSAID + PPI or misoprostol Selective COX-2 inhibitor NSAID (if available)	Avoid NSAID or selective COX-2 inhibitor, if possible; use alternative therapy Nonselective NSAID or partially selective NSAID + PPI or misoprostol Selective COX-2 inhibitor NSAID (if available) + PPI or misoprostol
High CV risk (patient requires low-dose aspirin, no NSAID	No prophylaxis required	PPI or misoprostol	PPI or misoprostol
High CV risk (patient requires low-dose aspirin) and NSAID	Naproxen + PPI or misoprostol	Naproxen + PPI or misoprostol	Avoid NSAID or selective COX-2 inhibitor, if at all possible; use alternative therapy If antiinflammatory drug is needed and CV risk is >GI risk, use naproxen and aspirin + PPI or misoprostol If antiinflammatory drug and aspirin are needed and GI risk is >CV, use selective COX-2 inhibitor + PPI or misoprostol

COX-2, cycloxygenase-2 inhibitor; NSAID, nonsteroidal antiinflammatory drug; PPI, proton pump inhibitor; CV, cardiovascular; GI, gastrointestinal.
Data from references 12 to 15, 18, 19, and 59.

and azithromycin or erythromycin should not be substituted for clarithromycin. Antisecretory drugs enhance antibiotic activity and stability by increasing intragastric pH and by decreasing intragastric volume thereby enhancing the topical antibiotic concentration.[27]

Proton Pump Inhibitor–Based Three-Drug Regimens

PPI-based triple therapy (see Table 40–8) is the initial treatment of choice for eradicating *H. pylori* (see Table 40–7).[5,25–29] The regimens that combine either clarithromycin and amoxicillin or clarithromycin and metronidazole are more effective than the amoxicillin-metronidazole regimen. In most cases, increasing the antibiotic dosage does not improve eradication rates. The clarithromycin-amoxicillin regimen is preferred initially (see Table 40–7), but metronidazole should be substituted for amoxicillin for penicillin-allergic patients unless alcohol is consumed.[5,25–27] Unfortunately, eradication rates for PPI-based triple therapy have declined substantially in recent years in North America and Europe due primarily to an increase in clarithromycin-resistant *H. pylori* strains (see the section Factors that Contribute to Unsuccessful Eradication).[5,25–27] Other antibiotics and antibiotic combinations have been investigated, but these regimens should not be used as initial treatment in the United States until well-designed trials confirm their effectiveness.[5,27]

The recommended duration of therapy in the United States is 10 to 14 days, but the 14-day regimen is preferred in light of the decreasing eradication rate with the PPI-based triple therapy regimens containing clarithomycin.[5] Although a 7-day course has been approved by the FDA and is used in Europe, the longer treatment periods favor higher eradication rates and are less likely to be associated with antimicrobial resistance.[5,25–27]

CLINICAL CONTROVERSY

Some clinicians favor an initial 7-day *H. pylori* regimen even though clinical guidelines suggest a longer treatment course. These clinicians believe that the shorter treatment period enhances the compliance of a complicated drug regimen. Others adhere to clinical guidelines and recommend a 10- or 14-day treatment period that favors higher eradication rates in the compliant patient and is less likely to contribute to antimicrobial resistance.

The PPI is an integral part of the three-drug regimen and should be taken 30 to 60 minutes before a meal along with the two antibiotics (see Table 40–8).[5,32] Prolonged PPI treatment beyond 2 weeks after eradication is usually not necessary for ulcer healing. A single daily dose of a PPI may be less effective than a twice daily dose.[33] Substitution of one PPI for another is acceptable and does not enhance or diminish *H. pylori* eradication.[32,34] An H_2RA should not be substituted for a PPI, as H_2RA is associated with lower eradication rates.[35,36] Pretreatment with a PPI does not influence *H. pylori* eradication.[37]

Bismuth-Based Four-Drug Regimens

Bismuth-based quadruple therapy (see Table 40–8) is recommended as an alternative first-line eradication therapy (see Table 40–7) for those allergic to penicillin.[5,25–29] Although this regimen may be used initially, it is often reserved as a second-line therapy after treatment failure with the PPI-based clarithromycin-amoxicillin regimen (see the section Eradication of *H. Pylori* After Initial Treatment Failure). Eradication rates for bismuth-based quadruple therapy (bismuth salicylate, metronidazole, tetracycline, and either a PPI or H_2RA) are similar to those achieved with PPI-based triple therapy.[5,27,38] Eradication rates are comparable when bismuth subcitrate potassium (biskalcitrate) is substituted for bismuth subsalicylate (see Table 40–8).[39] Substitution of amoxicillin for tetracycline lowers the eradication rate and is usually not recommended.[38] Substitution of clarithromycin 250 to 500 mg four times a day for tetracycline yields similar results but increases adverse effects. Bismuth salts have a topical antimicrobial effect.[1] The antisecretory drug hastens ulcer healing and relives pain in patients with an active ulcer. All medications except the PPI should be taken with meals and at bedtime.

The original bismuth-based regimens contained an H_2RA in place of a PPI, but a recent metaanalysis indicated that quadruple therapy with a PPI provides greater efficacy and permits a shorter treatment duration (7 days) when compared with the H_2RA-based regimens (10 to 14 days).[40] However. a 10- to 14-day duration is recommended in the United States as it generally provides higher eradication rates.[5] When treating an active ulcer, the antisecretory drug is usually continued for 2 (PPI) to 4 (H_2RA) weeks after stopping bismuth and antibiotics.

Bismuth-based quadruple therapy is the treatment of choice when medication costs are of overriding importance. However, major concerns include a 4-time-a-day dosing regimen (see Table 40–8), poor medication adherence, and frequent adverse effects. Although minor adverse effects are more common, the frequency of moderate or severe adverse effects is similar to those reported for the PPI-based triple therapy.[41]

Sequential Therapy Sequential therapy is a new form of eradication therapy whereby the antibiotics are administered in a sequence rather than all together.[5,26,29] The rationale for sequential therapy is to initially treat with antibiotics that rarely promote resistance (e.g., amoxicillin) to reduce the bacterial load and preexisting resistant organisms and then to follow with different antibiotics (e.g., clarithromycin and metronidazole) to kill the remaining organisms.[1] Treatment consists of a PPI and amoxicillin for 5 days followed by a PPI, clarithromycin, and metronidazole for an additional 5 days (see Table 40–8).[5,26,42] Although this regimen has achieved eradication rates that are superior to the PPI-based three-drug regimens containing clarithromycin,[42] the regimen requires a change in medication mid-treatment, which may contribute to nonadherence.[43] The advantages of sequential therapy need to be confirmed in the United States before it can be recommended as a first-line *H. pylori* eradication therapy (see Table 40–7).[5,26,27]

Eradication of *H. Pylori* After Initial Treatment Failure

H. pylori eradication is often more difficult after initial treatment fails and successful eradication after retreatment is extremely variable.[5,44] Treatment failures should be referred to a gastroenterologist for further diagnostic evaluation. Second-line (salvage) treatment should (a) use antibiotics that were not previously used during initial therapy; (b) use antibiotics that are not associated with resistance; (c) use a drug that has a topical effect such as bismuth; and (d) extend the duration of treatment to 14 days.[5,44,45] The most commonly used second-line therapy, after unsuccessful initial treatment with a PPI-amoxicillin-clarithromycin regimen, is a 14-day course of the PPI-based quadruple therapy (see Table 40–8).[5,26,27,45] A levofloxacin-containing regimen (see Table 40–8) may be an alternative second-line eradication regimen and may be better tolerated than PPI-based quadruple therapy (see Table 40–7).[46] Additionally, the levofloxacin regimen may serve as an alternative to PPI-clarithromycin-metronidazole usually recommended in penicillin allergic patients.[47] However, concerns about using fluoroquinolones for *H. pylori* eradication are related to the development of resistance and adverse effects such as tendonitis and hepatoxicity.[26] Other second-line regimens which include rifabutin and furazolidone are discussed elsewhere.[5,25–27]

Factors That Predict *H. Pylori* Eradication Outcomes

Factors that predict *H. pylori* eradication outcomes include antibiotic resistance, poor medication adherence, short duration of therapy, CagA status, high bacterial load, low intragastric pH, and genetic polymorphism.[5,45,48–50] Medication adherence decreases with multiple medications, increased frequency of administration, intolerable adverse effects, and costly drug regimens. One metaanalysis reported that CYP2C19 polymorphism may alter the effect of PPIs on gastric acid secretion thereby influencing eradication outcomes.[49] Tolerability varies with different regimens.[1,5] Common adverse effects include nausea, vomiting, abdominal pain, diarrhea and taste disturbances (metronidazole and clarithromycin). Adverse effects with metronidazole are dose-related (especially when >1 g/day) and include a disulfiram-like reaction with alcohol. Tetracycline may cause photosensitivity and should not be used in children because of possible tooth discoloration. Bismuth salts may cause darkening of the stool and tongue. Antibiotic-associated colitis occurs occasionally. Oral thrush and vaginal candidiasis may also occur.

An important predictor of *H. pylori* eradication is the presence or absence of resistant microrganisms.[5,50–52] United States data from 1993 to 1999 report resistance rates among *H. pylori* strains for metronidazole (37%), clarithromycin (10%), and amoxicillin (1.4%).[51] Data from 1998 to 2002 reveal rates of 25% for metronidazole, 13% for clarithromycin, and 0.9% for amoxicillin.[52] It is possible that the increased rate of clarithomycin resistance partially explains the decrease in efficacy of clarithomycin-containing regimens. The clinical importance of metronidazole resistance remains uncertain, as resistance can be overcome by using higher dosages and combining metronidazole with other antibiotics.[5] Resistance to tetracycline and amoxicillin is uncommon.[5] Resistance to bismuth has not been reported. The role of antibiotic sensitivity testing prior to initiating *H. pylori* treatment has not been established.

Probiotics

Probiotics (e.g., strains of *Lactobacillus* and *Bifidobacterium*) and foodstuffs (e.g., cranberry juice and some milk proteins) with bioactive components have been used proactively to control *H. pylori* colonization in at-risk individuals and, when taken as a supplement to eradication therapy, may have a role in improving *H. pylori* eradication and reducing the adverse effects of PPI-based triple therapy.[53–55] However, the administration of probiotics alone does not eradicate *H. pylori* infection. In the future, the regular intake of probiotics may constitute a low-cost alternative for individuals who are at-risk for *H. pylori* infection and, in combination with antibiotics, augment eradication rates. These preliminary data are encouraging and warrants more research in this area.

Treatment of NSAID-Induced Ulcers

Nonselective NSAIDs should be discontinued (when possible) upon confirmation of an active ulcer. If the NSAID is stopped, most uncomplicated ulcers heal with standard regimens of an H_2RA, PPI, or sucralfate (see Table 40–9).[1,13,29] However, the PPIs are usually preferred because they provide more rapid symptom relief and ulcer healing. If the NSAID is continued despite ulceration, consideration should be given to reducing the NSAID dose, switching to acetaminophen or a nonacetylated salicylate or to using a more selective COX-2 inhibitor (see Table 40–3). The PPIs are the drugs of choice when the NSAID is continued, as potent acid suppression is required to accelerate ulcer healing.[1,13,29] If the ulcer is *H. pylori*–positive, eradication should be initiated with a regimen that contains a PPI.[1,13,29]

Strategies to Reduce the Risk of NSAID Ulcer and GI Complications There are three therapeutic approaches to reducing the risk of NSAID ulcers and related upper GI complications (see Table 40–10). Medical cotherapy with either a PPI or misoprostol decreases ulcer risk and GI complications in high-risk patients.[12–14,16,19,29] The use of a selective COX-2 inhibitor instead of a nonselective NSAID also decreases risk of ulcers and upper GI events.[12–14,16,18,19,29] Unfortunately, these strategies do not completely eliminate ulcers and complications for patients at the "highest risk." When selecting a gastroprotective strategy, the GI benefits be must be balanced against the cardiovascular risks associated with selective COX-2 inhbitor NSAIDs, nonselective NSAIDs, and concomittant antiplatelet therapy.[12–16] Strategies aimed at reducing the topical irritant effects of nonselective NSAIDs, e.g., prodrugs, slow-release formulations, and enteric-coated products, do not prevent ulcers or GI complications.

Misoprostol Cotherapy Misoprostol, 200 mcg orally 4 times per day, reduces the risk of NSAID-induced gastric and duodenal ulcer, and related upper GI complications, but diarrhea and abdominal cramping limit its use.[12,16,56] Because a dosage of 200 mcg 3 times per day is comparable in efficacy to 800 mcg/day, the lower dosage should be considered for patients unable to tolerate the higher dose.[12,16] Reducing the misoprostol dosage to 400 mcg per day or less to minimize diarrhea compromises its gastroprotective effects. A fixed combination of misoprostol 200 mcg and diclofenac (50 mg or 75 mg) may enhance compliance, but the flexibility to individualize drug dosage is lost. A large clinical trial in rheumatoid arthritis patients provided the most compelling evidence that misoprostol reduces the risk of upper GI complications for high-risk patients.[57]

Proton Pump Inhibitor Cotherapy 4 PPI cotherapy reduces NSAID-related gastric and duodenal ulcer risk and is better tolerated than misoprostol.[12–14,16,56] All PPIs are effective when used in standard dosages (see Table 40–9). Although head-to-head comparative trials are few, there are limited data to indicate that PPIs are superior to standard H_2RA dosages.[12,13,16,] When lansoprazole (15 or 30 mg/day) was compared with misoprostol 800 mcg/day or placebo, both dosages of lansoprazole and misoprostol effectively reduced ulcer recurrence, although the PPI was better tolerated.[58] A greater proportion of those in the misoprostol group reported treatment-related adverse events and withdrew early from the study. Results from observational studies and metaanalyses indicate the PPIs reduce the risk of NSAID-related ulcer bleeding.[12,16,19,59]

H_2-Receptor Antagonist Cotherapy Standard H_2RA dosages (e.g., famotidine 40 mg/day) are effective in reducing NSAID-related duodenal ulcer but not gastric ulcer (the most frequent type of ulcer associated with NSAIDs).[12,13,16] Higher dosages (e.g., famotidine 40 mg twice daily, ranitidine 300 mg twice daily) may reduce the risk of gastric and duodenal ulcer, but studies comparing double dosages with PPIs or misoprostol are not available.[12,13] One study suggests that famotidine 20 mg twice daily may be an alternative to PPIs for patients taking low cardioprotective dosages of aspirin, but additional studies are required to confirm these findings.[60] The H_2RAs are not recommended as prophylactic cotherapy because it is likely that they are not as effective as the PPIs or misoprostol in preventing NSAID-induced gastric ulcer and related GI complications.[16] An H_2RA, however, may be used to relieve NSAID-related dyspepsia.

Cyclooxygenase-2 Inhibitors Two large outcome trials have compared celecoxib[61] and rofecoxib[62] to nonselective NSAIDs. Patients in the Celecoxib Long-term Arthritis Safety Study (CLASS) trial who were taking celecoxib and required cardioprotection

(antiplatelet effects of aspirin) were permitted to take low-dose aspirin.[61] Although a 6-month analysis found a nonsignficant reduction in ulcer complications with celecoxib when compared with ibuprofen and diclofenac, results after 1 year found no difference between the groups. Today, celecoxib is not considered a selective COX-2 inhibitor (Table 40–3) by the FDA as it contains the same GI warnings as the nonselctive and patially selective NSAIDs.[63] A post hoc analysis confirmed that any gastroprotective benefits of celecoxib were negated in aspirin users. Similar effects have been observed with rofecoxib.

The Vioxx Gastrointestinal Outcomes Research (VIGOR) trial excluded aspirin users and found that ulcers and ulcer-related complications were significantly reduced with rofecoxib when compared with naproxen.[62] However, there was an increased number of nonfatal myocardial infarctions observed in the rofecoxib group compared with those taking naproxen. It was initially suggested that the lack of antiplatelet effects from rofecoxib, in contrast to the platelet inhibition associated with naproxen, was responsible for the increased thrombotic events observed in the rofecoxib group. Rofecoxib was later withdrawn from the market following an interim analysis of a study to prevent colorectal adenomas that revealed an increased risk of myocardial infarction and thrombotic stoke with rofecoxib when compared with placebo.[64] Subsequently, valdecoxib was withdrawn from the market amid concerns about cardiovascular risk.

Cardiovascular safety was also evaluated in the CLASS trial, but serious cardiovascular thromboembolic events were no different between celecoxib and the comparative nonselective NSAIDs. In contrast, the results of a metaanalysis of randomized trials of COX-2 inhbitor NSAIDs reported a dose-dependent increase in cardiovascular events with all COX-2 inhibitor NSAIDs, including celecoxib.[65] Increased cardiovascular risk appears to be dependent on a number of factors including increased COX-2 selectivity, higher dosages, and a longer duration of treatment.[12,18,19] Thus, the lowest effective celecoxib dose should be used for the shortest duration of time. Dyspepsia and abdominal pain, fluid retention, hypertension, and renal toxicity are associated with the COX-2 inhibitors and nonselective NSAIDs.[1]

COX-2 Inhibitor Versus NSAID plus PPI 5 There are limited data that suggest that for high-risk, *H. pylori*–negative patients, a COX-2 inhibitor NSAID may be as beneficial as a nonselective NSAID plus a PPI in reducing NSAID-related ulcer complications.[12,18,19] However, neither the COX-2 inhibitor NSAID nor the NSAID plus a PPI will eliminate upper GI events for these patients. Combining a COX-2 inhibitor NSAID with a PPI may be considered for very high-risk patients, but this regimen is likely to be of modest benefit.[12,18]

Gastrointestinal and Cardiovascular Safety Issues

There is no difference in cardiovascular risk between the selective COX-2 inhitor NSAIDs and the nonselective or partially selective NSAIDs, with the exception of naproxen[12,18,65] Thus, individual patient risk factors for NSAID-related GI bleeding and cardiovascular events must be weighed when determining treatment (see Table 40–10). Naproxen is preferred to nonnaproxen NSAIDs and COX-2 inhbitors because of its comparative cardiovascular safety and not because of its GI safety profile. There is insufficient evidence regarding the preferred NSAID for patients also taking low-dose aspirin.[14] Clopidogrel should not be substituted for low-dose aspirin in order to reduce recurrent GI bleeding as it is inferior to a PPI plus low-dose aspirin.[13] Despite limited evidence to suggest an interaction via the hepatic cytochrome P450 (CYP450) pathway, combining a PPI and clopidogrel with or without low-dose aspirin results in less GI bleeding.[13] Ongoing studies for patients with cardiovascular disease should provide the necessary information to help resolve these issues. The lowest possible daily dose of a COX-2 inhibitor should be used as the cardiovascular risk may be dose dependent. However, no studies, to date, have evaluated the safety of low-dose COX-2 inhibitor NSAIDs for patients with or at risk for cardiovascular disease. In the future, there will be new formulations and classes of NSAIDs and COX-2 inhibitors with an improved GI and cardiovascular safety profile.[66] Until then patients who take NSAIDs or COX-2 inhibitors should be counseled about the signs and symptoms of upper GI bleeding and major cardiovascular events and what they should do if they occur.

Treatment of non-*H. Pylori*, non-NSAID Ulcers

Very few individuals have non-*H. pylori*, non-NSAID (idiopathic) ulcers.[29,67,68] Patients should be double-checked to verify that they are *H. pylori* negative and that they are not taking ulcerogenic medications. Possible explanations for *non-H.pylori*, non-NSAID ulcers include gastric hypersecretion, gastric outlet obstruction, genetic predisposition, concomitant diseases (see Table 40–2), and heavy tobacco use. Treatment should be initiated with conventional ulcer healing therapy (see Table 40–9). Although standard H_2RA or sucralfate dosage regimens heal the majority of gastric and duodenal ulcers in 6 to 8 weeks, PPIs provide comparable ulcer healing rates in 4 weeks.[32] A higher daily dose or a longer treatment duration is sometimes needed to heal larger gastric ulcers. Antacids are not used as single agents to heal ulcers because of the high volume and frequent doses required. When conventional antiulcer therapy is discontinued after ulcer healing, most patients develop a recurrent ulcer within 1 year.[32] Maintenance therapy may be required to prevent ulcer recurrence.

Long-Term Maintenance of Ulcer Healing

Continuous antiulcer therapy is aimed at the long-term maintenance of ulcer healing and the prevention of ulcer-related complications. Because *H. pylori* eradication dramatically decreases ulcer recurrence, continuous maintenance therapy is primarily used to treat high-risk patients who failed *H. pylori* eradication, have a history of ulcer-related complications, have frequent recurrences of *H. pylori*–negative ulcers, and are heavy smokers or NSAID users. For most patients, standard maintenance dosages (see Table 40–9) are effective.[32]

Treatment of Refractory Ulcers

Ulcers are considered refractory to therapy when symptoms, ulcers, or both persist beyond 8 to 12 weeks despite conventional treatment or when several courses of *H. pylori* eradication fail.[1,45] Poor patient compliance, antimicrobial resistance, cigarette smoking, NSAID use, gastric acid hypersecretion, or tolerance to the antisecretory effects of an H_2RA (see the section Antiulcer Agents) may contribute to refractory PUD. Patients with refractory ulcers should undergo upper endoscopy to confirm a nonhealing ulcer, exclude malignancy, and assess *H. pylori* status. *H. pylori*–positive patients should receive eradication therapy (see the secton Treatment of *Helicobacter pylori*–Associated Ulcers). In *H. pylori*–negative patients, higher PPI dosages (e.g., omeprazole 40 mg/day) heal the majority of ulcers. Continuous treatment with a PPI is often necessary to maintain healing, as refractory ulcers recur when therapy is discontinued or the dose is reduced. Switching from one PPI to another is not beneficial. Patients with refractory gastric ulcer may require surgery because of the possibility of malignancy.

Antiulcer Agents

Proton Pump Inhibitors The PPIs (omeprazole, esomeprazole, lansoprazole, dexlansoprazole, rabeprazole, and pantoprazole) dose-dependently inhibit basal and stimulated gastric acid secretion.[32] When PPI therapy is initiated, the degree of acid suppression increases over the first 3 to 4 days of therapy, as more proton pumps are inhibited.[32] Because PPIs inhibit only those proton pumps that are actively secreting acid, they are most effective when taken 30 to 60 minutes before meals.[32] The duration of acid suppression is a function of binding to the H^+/K^+-adenosine triphosphatase (ATPase) enzyme and is longer than their elimination half-lives.[32] Symptomatic acid rebound upon withdrawal of a PPI has been reported in healthy volunteers after 8 weeks of treatment.[1,69]

Various PPI dosage forms and formulations exist and (see Table 40–11) include the delayed-release enteric-coated dosage forms that have pH-sensitive granules contained in gelatin capsules (omeprazole, esomeprazole, prescription and nonprescription lansoprazole, and dexlansoprazole), rapidly disintegrating tablets (lansoprazole), and delayed release enteric-coated tablets (rabeprazole, pantoprazole, and nonprescription omeprazole).[32] The pH-sensitive enteric coating prevents degradation and premature protonation of the drug in stomach acid but dissolves at a higher pH in the duodenum where the drug is absorbed. Dexlansoprazole is formulated with a dual release mechanism that results in inhibition of proton pumps that become activated after initial release of the medication.[70,71] Omeprazole is also available as an immediate release formulation (oral suspension, oral capsule) containing sodium bicarbonate, which raises intragastric pH and protects omeprazole from acid degradation in the stomach thus permitting rapid absorption from the duodenum.[72] Intravenous products available in the United States include pantoprazole and esomeprazole.

Five of the PPIs provide similar rates of ulcer-healing (dexlansoprazole has not been labeled at this time for these indications), maintenance of ulcer healing, and symptom relief when used in recommended dosages (see Table 40–9). When higher dosages are indicated, the daily dose should be divided in order to obtain better 24-hour control of intragastric pH. A dosage reduction is unnecessary for patients with renal impairment or in older adults but should be considered in severe hepatic disease.[32] The short-term adverse effects of the PPIs are similar to those observed with the H_2RAs and include headache, nausea, and abdominal pain.[32] Because the immediate-release formulations contain sodium bicarbonate, they are contraindicated for patients with metabolic alkalosis and hypocalemia.[72] The sodium should also be taken into consideration for patients who are on sodium-restricted diets, e.g., congestive heart failure.

Drug Interactions All PPIs increase intragastric pH and may alter the bioavailability of orally administered drugs, such as ketoconazole (weak bases) and digoxin, or pH-dependent dosage forms.[32,73] This interaction is especially important with atazanavir, a protease inhibitor. Concomitant use with a PPI can significantly reduce the oral bioavailability of atazanavir and potentially lead to therapeutic failure and viral resistance in patients infected with HIV.[74] Omeprazole and esomeprazole selectively inhibit the hepatic CYP2C19 pathway and may decrease the elimination of phenytoin, warfarin, diazepam, and carbamazepine.[32] The PPIs may increase the metabolic clearance and decrease the GI absorption of levothyroxine resulting in increased thyroid-stimulating hormone levels and a corresponding increase in the levothyroxine dose.[75] A review of the FDA database for the years 1997 to 2001 reveals that drug interactions with PPIs are rare and usually do not constitute a major clinical risk.[76]

One of the most perplexing potential PPI drug interactions is with the antiplatelet drug clopidogrel. This interaction is especially important given recent consensus guidelines that recommend the use of a PPI for high-risk patients on antiplatelet therapies to prevent ulcers and related GI bleeding.[13] Clopidogrel, a prodrug, is converted to its active form through CYP2C19. PPIs may attenuate the antiplatelet effect of clopidogrel by inhibiting or competing for this metabolic pathway. FDA safety guidelines recommend that the coadministration of omeprazole, omeprazole/sodium bicarbonate, or esomeprazole with clopidogrel be avoided because they reduce the effectiveness of clopidogrel.[77–79] Details of new studies

TABLE 40-11 Proton Pump Inhibitor Formulations and Options for Administration

	Omeprazole	Esomeprazole	Lansoprazole	Pantoprazole	Rabeprazole	Dexlansoprazole
Commercially available oral formulations

Extemporaneous preparation of delayed-release PPI in bicarbonate	X		X	X		
Parenteral formulations						
Intravenous	Not available in the United States	X		X		

X, product is available.

[a]Omeprazole is available as delayed-release enteric-coated pellets in a capsule or as immediate-release capsule that contains 20 or 40 mg of omeprazole with 1100 mg sodium bicarbonate (equivalent to 304 mg of sodium). Because 20 and 40 mg dosages contain the same amount of bicarbonate, two 20 mg capsules should not be substituted for the 40 mg immediate-release omeprazole-bicarbonate capsule.

[b]Omeprazole oral tablets are available as 20 mg delayed-release nonprescription tablets.

[c]Omeprazole oral suspension is available as 20 or 40 mg omeprazole with 1,680 mg sodium bicarbonate (equivalent to 460 mg of soidum). Because 20 and 40 mg dosages contain the same amount of bicarbonate, two 20 mg packets should not be substituted for the 40 mg immediate-release omeprazole-bicarbonate packet.

[d]No published information; based on omeprazole data.

[e]Dexlansoprazole is available as a dual delayed-release formulation in capsules for oral administration. The capsule contains dexlansoprazole in a mixture of two types of enteric-coated granules with different pH-dependent dissolution profiles.

Data from references 32, 70, and 72.

performed by the manufacturer and submitted to the FDA, as well as warnings regarding omeprazole, esomeprazole, and other interacting drugs (e.g., cimetidine) are contained in the clopidogrel package insert.[80] A reduced antiplatelet effect of clopidogrel may also result from genetic polymorphisms of the CYP2C19 pathway leading to decreased biotransformation of the drug to its active form.[81,82] Whether the use of other PPIs such as pantoprazole, lansoprazole, dexlansoprazole, and rebeprazole interact with clopidogrel remains uncertain as the capacity to inhibit CYP2C19 varies among these PPIs.[83,84] While some reports suggest a "class effect" among the different PPIs, other pharmacodynamic studies suggest an interaction with omeprazole and esomeprazole but not with pantoprazole.[83,84] Because of the uncertainty of the effect of the PPI-clopidogrel interaction on clinical outcomes and the extent to which other PPIs may interact with clopidogrel, caution is warranted. Until more compelling data becomes available, patients should have an acceptable indication for a PPI recognizing that risk versus benefit must be weighed on an individual basis. If a PPI is absolutely necessary, the use of omeprazole and esomeprazole should be avoided.

CLINICAL CONTROVERSY

Some clinicians believe that the antiplatelet effect of clopidogrel is attenuated by omeprazole and that there is an increased risk of adverse cardiac events when these medications are taken concomitantly. Strategies to avoid this interaction for patients at risk of NSAID-related GI events include switching omeprazole to another PPI or substituting an H_2RA for the PPI. Others believe that the use of a PPI (if indicated) and clopidogrel is not a safety concern and that it is not necessary to switch omeprazole to another PPI.

Potential Risks and Long-Term Safety Issues Numerous potential risks and safety issues (see Table 40–12) have been associated with the long-term use of PPIs as a consequence of prolonged hypergastrinemia and chronic hypochlorhydria.[32,85–88] In most cases, causality is difficult to ascertain because of the study design, confounding variables, and subject selection. All of the PPIs dose-dependently increase serum gastrin concentrations two- to fourfold as a function of their potent acid-inhibitory effect.[32,85] Fasting gastrin elevations are usually within the normal range and return to baseline within 1 month of discontinuing the drug. In humans, PPIs may lead to enterochromaffin-like (ECL) hyperplasia as a result of the hypergastrinemia, but there is no evidence that these changes result in dysplasia, carcinoid tumors, or gastric adenocarcinoma.[85,86] Although long-term PPI therapy in *H. pylori*–positive individuals is associated with progressive atrophic gastritis, there is insufficient data to link chronic PPI use with gastric cancer in *H. pylori*–positive patients.[85,86] Despite theoretical and in vitro data, there is no evidence to support an association between PPIs and colonic polyps or colorectal cancer.[85,86] Bacterial overgrowth occurs in the stomach as a consequence of hypochlorhydria and may lead to carcinogenic *N*-nitroso compounds in animals but is unlikely to result in significant gastric nitrosation in humans.[85,88]

Chronic PPI therapy may be associated with an increased risk of infection and nutritional deficiences.[85–87] Gastric acid (low stomach pH) plays an important role in the defense against bacterial colonization of the stomach and in nutrient absorption. Acid suppression has been implicated as a risk factor for community acquired pneumonia (CAP) and enteric infections (*Clostridium difficile, Salmonella, Campylobacter*).[86] Three case-controlled studies demonstrate a higher adjusted relative risk of CAP for patients currently using PPIs compared with controls.[89–91] The results of these retrospectively designed studies, however, need to be interpreted cautiously because of the variability in the length of therapy for current PPI users and the inclusion of older (>60 years of age) patients with concomitant comorbidities. A systematic review of the literature has linked PPIs with various enteric infections, but the most convincing data was with *C. difficile*.[92] It is likely that sustained elevations in intragastric pH facilitate the survival of *C. difficile* spores. However, the magnitude of risk varies and causality is difficult to establish. The risk of various infections associated with PPI therapy can not be firmly established until the results of large prospective studies are made available.

TABLE 40-12 Potential Risks and Safety Issues Associated with the Proton Pump Inhibitors

Gastric cancers or malignancy
Carcinoid tumors
Atrophic gastritis
Adenocarcinoma
Bacterial overgrowth
Increase in N-nitroso compounds from ingested nitrates (carcinogenic)
Enteric infections *(Clostridium difficile, Salmonella typhimurium, and Campylobacter jejuni)*
Community acquired pneumonia
Decreased nutrient absorption:
Iron
Calcium
Cyanocobalamin (vitamin B12)
Osteoporosis and related fractures

Data from references 32, 85 to 88.

The absorption of Vitamin B12, dietary iron, and calcium requires an acidic environment and may be adversely affected by PPI-induced prolonged hypochlorhydria.[86] Although a few studies have investigated the long-term use of PPIs on Vitamin B12 and iron absorption, the clinical importance of their effect on absorption has not been established, and monitoring of B12 and iron levels cannot be recommended.[86] However, adequate supplementation and monitoring should be considered in high risk populations (e.g., older patients, vegetarians, alcoholism) who may be already depleted.[85,86] High PPI dosage and long-term therapy have been associated with an increased risk of hip, wrist and spine fractures related to reduction in calcium absorption.[26,93] Although the results of the studies vary, the FDA has revised the warnings and precautions of prescription and nonprescription PPIs to reflect this potential risk.[93] Bone density tests for osteoporosis screening, calcium supplementation, or other precautions cannot be recommended solely based on chronic PPI therapy.[94] However, it is appropriate to screen and treat older patients for osteoporosis regardless of whether they are receiving long-term PPI therapy.

H_2-Receptor Antagonists Ulcer healing is comparable among H_2RAs (cimetidine, famotidine, nizatidine, and ranitidine) with equipotent multiple daily doses or a single full dose given after dinner or at bedtime (see Table 40–9), but tolerance to their antisecretory effect may occur.[95] Twice-daily administration suppresses daytime acid and benefits patients with daytime ulcer pain. Cigarette smokers may require higher doses or a longer duration of treatment. H_2RAs are eliminated renally and therefore a dosage reduction is recommended for patients with moderate to severe renal failure.[96] The short- and long-term safety of all four H_2RAs is similar.[1] Thrombocytopenia, the most common

hematologic adverse effect, is reversible and occurs with all four H_2RAs. However, the propensity for H_2RAs to cause thrombocytopenia is likely overestimated.[97] Cimetidine inhibits several CYP450 isoenzymes, resulting in numerous drug interactions (e.g., theophylline, lidocaine, phenytoin, warfarin, and clopidogrel).[77,96] Ranitidine has less potential for hepatic CYP450 drug interactions, while famotidine and nizatidine do not interact with drugs metabolized by the hepatic CYP450 pathway.[96] The H_2RAs decrease acid secretion and may alter the bioavailability of orally administered drugs, similar to that seen with the PPIs.

Sucralfate Sucralfate heals peptic ulcers, but is not widely used today for this indication.[1] Deterrents to its use include the requirement for multiple doses per day, large tablet size, and the need to separate the drug from meals and potentially interacting medications. Drug interactions can be minimized by giving the interacting drug at least 2 hours before sucralfate. Alternative therapy is warranted for patients taking oral fluoroquinolones. Constipation may be troublesome especially in older individuals. Seizures may occur in dialysis patients taking aluminum-containing antacids. Hypophosphatemia may develop with long-term treatment. Gastric bezoar formation has also been reported.

Prostaglandins Misoprostol, a synthetic prostaglandin E_1 analog, moderately inhibits acid secretion and enhances mucosal defense.[1,98] Antisecretory effects are dose dependent over the range of 50 to 200 mcg; cytoprotective effects occur in humans at doses of greater than 200 mcg. Because protective effects occur at higher doses, it is difficult to establish the protective effect independent of the antisecretory action. Although not recommended in the United States, a dose of 200 mcg 4 times daily or 400 mcg twice daily heals duodenal ulcers and gastric ulcers comparable to standard H_2RA or sucralfate regimens. Diarrhea, the most troublesome adverse effect, is dose dependent and develops in 10% to 30% of patients.[1,98] Abdominal cramping, nausea, flatulence, and headache typically accompany the diarrhea. Taking the drug with or after meals and at bedtime may minimize the diarrhea. Misoprostol is contraindicated in pregnant women because it is uterotropic and produces uterine contractions that may endanger pregnancy.[98] If misoprostol is prescribed to women in their childbearing years, contraceptive measures must be confirmed and a negative serum pregnancy test should be documented within 2 weeks of initiating treatment. Patients should be counseled about the GI effects and the need to avoid magnesium antacids, as they may increase the propensity for GI adverse effects.

Bismuth Preparations Bismuth subsalicylate and bismuth subcitrate potassium (biskalcitrate) are the only available bismuth salts in the United States.[1,96] Possible ulcer-healing mechanisms include an antibacterial effect, a local gastroprotective effect, and stimulation of endogenous prostaglandins. Bismuth salts do not inhibit or neutralize acid. Bismuth subsalicylate is regarded as safe and has few adverse effects when taken in recommended dosages. Because renal insufficiency may decrease bismuth elimination, bismuth salts should be used with caution in older patients and in renal failure. Bismuth subsalicylate may cause salicylate sensitivity or bleeding disorders and should be used with caution for patients receiving concurrent salicylate therapy. Bismuth salts impart a black color to stool and possibly the tongue (liquid preparations).

Antacids Antacids neutralize gastric acid, inactivate pepsin, and bind bile salts.[96,98] Aluminum-containing antacids also suppress *H. pylori* and enhance mucosal defense. The GI adverse effects are most common and are dose dependent. Magnesium salts cause an osmotic diarrhea, whereas aluminum salts cause constipation. Diarrhea usually predominates with magnesium/aluminum preparations. Aluminum-containing antacids (except aluminum phosphate) form insoluble salts with dietary phosphorus and interfere with phosphorus absorption. Hypophosphatemia occurs most often for patients with low dietary phosphate intake (e.g., malnutrition or alcoholism). Combined treatment with sucralfate may amplify the hypophosphatemia and aluminum toxicity.

Magnesium-containing antacids should not be used for patients with a creatinine clearance of less than 30 mL/min because magnesium excretion is impaired, which may lead to toxicity. Hypercalcemia may occur for patients with normal renal function taking more than 20 g/day of calcium carbonate and for patients with renal failure who are taking more than 4 g/day. The milk–alkali syndrome (hypercalcemia, alkalosis, renal stones, increased blood urea nitrogen, and increased serum creatinine concentration) occurs with high calcium intake for patients with systemic alkalosis produced by either ingestion of absorbable antacids (sodium bicarbonate) or prolonged vomiting. Antacids may alter the absorption and excretion of drugs when administered concomitantly.[96,98] Drug interactions may occur when antacids are administered with iron, warfarin, tetracycline, digoxin, quinidine, isoniazid, ketoconazole, or the fluoroquinolones. Most interactions can be avoided by separating the antacid from the oral drug by at least 2 hours.

Pharmacoeconomic Considerations

6 The eradication of *H. pylori* improves clinical outcomes and decreases the use of healthcare resources when compared with conventional antisecretory therapy.[99] Thus the costs of continued treatment and recurrence far outweigh the cost of *H. pylori* drug regimens. The cost-effectiveness of misoprostol cotherapy is greatest for patients with the highest risk for NSAID-related GI complications.[100] The addition of a PPI to both nonselective and partially selective NSAIDs or selective COX-2 inhibitor NSAIDs (if available) is highly cost-effective even for patients with low GI risk especially when the least expensive PPI is used.[101]

EVALUATION OF THERAPEUTIC OUTCOMES

7 Table 40–13 lists the recommendations for treating and monitoring patients with PUD. Relief of epigastric pain should be monitored throughout the course of treatment for patients with either *H. pylori*– or NSAID-related ulcers. Ulcer pain typically resolves in a few days when NSAIDs are discontinued and within 7 days upon initiation of antiulcer therapy. Most patients with uncomplicated PUD will be symptom free after treatment with any one of the recommended antiulcer regimens. The persistence, or recurrence, of symptoms within 14 days after the end of treatment suggests failure of ulcer healing or *H. pylori* eradication or an alternative diagnosis such as GERD. Most patients with uncomplicated *H. pylori*–positive ulcers do not require confirmation of ulcer healing or *H. pylori* eradication. However, eradication should be confirmed after treatment in individuals who are at risk for complications, for example, individuals who had a prior bleeding ulcer. The UBT is the preferred test to confirm *H. pylori* eradication when endoscopy is not indicated. Medication adherence should be assessed for patients who fail therapy. Because a large number of at-risk patients treated with NSAIDs do not receive adequate prophylaxis for GI complications, therapeutic outcomes can be improved by advocating preventive strategies. Patients on NSAIDs should be closely monitored for signs or symptoms of bleeding, obstruction, penetration, or perforation. A follow-up endoscopy is justified for patients with frequent symptomatic recurrence, refractory disease, complications, or suspected hypersecretory states.

TABLE 40-13 Recommendations for Treating and Monitoring Patients with *Helicobacter pylori*–Associated and Nonsteroidal Antiinflammatory Drug (NSAID)–Induced Ulcers

Helicobacter pylori-associated ulcer

1. Recommend drug treatment as presented in the chapter text. See Tables 40–7 and 40–8.
2. Assess patient allergies to determine if allergic to penicillin (or other antibiotics) so that drug regimens that contain penicillin (or other antibiotics) can be avoided. Avoid regimens that contain tetracycline in children.
3. Assess patient use of alcohol or alcohol-containing products with metronidazole and oral birth control medications with antibiotics and counsel appropriately.
4. Assess likelihood of nonadherence to the drug regimen as a cause of treatment failure.
5. Recommend a different antibiotic combination if *H. pylori* eradication fails and a second treatment is planned.
6. Inform the patient of change in stool color when bismuth salicylate is included in an *H. pylori* eradication regimen.
7. Assess and monitor patients for potential adverse effects, especially those associated with metronidazole, clarithromycin, and amoxicillin.
8. Assess and monitor patients for potential drug interactions, especially those receiving metronidazole, clarithromycin, or cimetidine.
9. Monitor patients for salicylate toxicity, especially patients receiving cotherapy with other salicylates and anticoagulants and patients with renal failure.
10. Monitor patients for persistent or recurrent symptoms within 14 days after completion of a course of *H. pylori* eradication therapy.
11. Provide patient education to patients who are receiving *H. pylori* eradication therapy and include why antibiotic and antiulcer combinations are used; when and how to take medications; adverse effects; alarm symptoms; the importance of adherence to the entire course of drug treatment; and contact their healthcare provider if alarm symptoms develop (e.g., blood in the stools, black tarry stools, vomiting, severe abdominal pain), or if symptoms persist or return after *H. pylori* eradication.

NSAID-induced ulcer

1. Recommend drug treatment as presented in the chapter text.
2. Assess risk factors for NSAID-induced ulcers and ulcer-related complications and recommend appropriate strategies for reducing ulcer risk (see Table 40–10).
3. Weigh patient risk factors for NSAID-related GI bleeding and cardiovascular events when selecting a strategy to reduce ulcer risk.
4. Recommend eradication treatment for *H. pylori*-positive patients taking NSAIDs.
5. Monitor patients for signs and symptoms of NSAID-related upper GI complications.
6. Assess and monitor patients for potential drug interactions and adverse effects (especially misoprostol).
7. Provide patient education to patients who are at risk of NSAID-induced ulcers or GI-related complications and include why cotherapy is used with nonselective NSAIDs; when and how to take medications; adverse effects; alarm symptoms; when to contact their healthcare provider; and the importance of adherence to drug treatment.

ZOLLINGER-ELLISON SYNDROME (ZES)

ZES is characterized by gastric acid hypersecretion and recurrent peptic ulcers that result from a gastrin-producing tumor (gastrinoma).[21,45] In the United States, ZES accounts for 0.1% to 1% of patients with duodenal ulcer; however, this may be an underestimation of the true incidence because of the heterogeneity of clinical manifestations.[21] Gastrinomas are classified as those associated with multiple endocrine neoplasia type 1 (MEN 1) or sporadic tumors, which have a greater tendency to behave as malignant tumors. In more than 80% of cases, gastrinomas are localized in an area referred to as the *triangle of gastrinomas*, which includes the convergence of the cystic duct and the common bile duct, the junction of the second and third portion of the duodenum, and the junction of the head and body of the pancreas.[21] More than 50% of the gastrinomas malignant, often with metastases to regional lymph nodes, liver, and bone.[21]

Zollinger-Ellison syndrome is suspected for patients with multiple ulcers and recurrent or refractory PUD, often accompanied by esophagitis or ulcer complications.[21,45] Ulcers occur most often in the duodenum but may involve the stomach or jejunum. Diarrhea occurs in about 50% of patients, and results from high concentrations of acid that overwhelm the duodenum's buffering capacity and damage to the mucosa.[21] Intraluminal acid also causes steatorrhea by inactivating pancreatic lipase and precipitating bile acids. Vitamin B12 malabsorption may result from reduced intrinsic factor activity. The diagnosis is established when the serum gastrin is higher than 1,000 pg/mL and the BAO ≥15 mEq/h for patients with an intact stomach (BAO ≥5 mEq/h for patients with previous gastric surgery) or when hypergastrinemia is associated with a gastric pH value of ≤2.[21] In situations in which the serum gastrin is between 100 and 1,000 pg/mL and gastric pH is ≤2, a secretin or calcium proactive test is used to aid the diagnosis.[21] Identification of the location of the tumor with imaging techniques is essential, as early surgical resection prior to liver metastases is often curative.[21] The widespread use of PPIs, although effective in reducing symptoms, may mask the clinical presentation and PPI-related hypergastrinemia may further complicate the diagnosis.[21]

Treatment is based on the presence or absence of peptic ulcers, esophagitis, diarrhea, and a gastrinoma, which may be malignant. The PPIs are the oral drugs of choice for managing gastric acid hypersecretion. Treatment should be instituted with omeprazole 60 mg/day (or an equivalent dose of the available PPIs) and should be adjusted based on individual patient response.[21] Dividing the daily dose and giving the PPI every 8 to 12 hours is most effective in controlling acid output and relieving symptoms. The goal of therapy for uncomplicated patients is to maintain BAO between 1 and 10 mEq/h, in the hour preceding the next dose of the PPI. In complicated cases, such as patients with MEN 1, GERD, or those who are undergoing partial gastrectomy, the BAO should be maintained below 5 mEq/h. A gradual reduction in PPI dose is recommended after the adequate control of gastric acid hypersecretion is achieved. Intravenous PPIs are used to suppress gastric acid secretion in patients who are unable to take oral PPIs. The somatostatin analogues, octreotide and lanreotide, directly inhibit the release of gastrin and gastric acid secretin and have been used with varying degrees of success.[21] However, these drugs are not considered first-line therapy as they are only available in the injectable form. Preliminary studies have found the long-acting depot formation of octreotide to be efficacious in the treatment of GI neuroendocrine tumors.[21] Patients with metastatic gastrinoma require tumor resection or treatment with chemotherapeutic agents.

UPPER GASTROINTESTINAL BLEEDING

There are about 160 cases of upper GI bleeding per 100,000 adults annually in the United States.[102] Despite a decreased incidence of PUD and improvements in the management of upper GI bleeding, the mortality rate associated with acute hemorrhage remains between 5% and 15%.[102–104] Upper GI bleeding is categorized as variceal or nonvariceal bleeding. Two common types of nonvariceal bleeding are bleeding from chronic peptic ulcers and bleeding from SRMD (stress gastritis, stress ulcer, or stress erosions), both of which are acid–peptic complications.[102–106] Upper GI bleeding associated with chronic PUD usually precedes hospital admission, whereas bleeding associated with SRMD develops in severely ill patients during hospitalization.[102,106]

The underlying pathophysiology of bleeding from a peptic ulcer or from SRMD is similar in that impaired mucosal defense in the presence of gastric acid and pepsin leads to mucosal

damage. In chronic PUD, *H. pylori* infection and NSAID use are the most important etiologic factors, whereas the primary pathogenic factor of SRMD in critically ill patients is thought to be mucosal ischemia which is a result of reduced gastric blood flow (decreased oxygen and nutrient delivery) resulting from splanchnic hypoperfusion.[1,102,106–108] Defense mechanisms are normally in place to protect the gastric mucosa against the damaging effects of gastric acid, pepsin, and bile (see the section Pathophysiology of Chronic PUD). However, these defense mechanisms become diminished in the face of the overwhelming physiologic stress from critical illness and coupled with mucosal ischemia and subsequent reperfusion injury along with gastric acid result in the rapid development of mucosal lesions.[106–107] In contrast to chronic PUD, stress-related mucosal lesions are characteristically asymptomatic, numerous, located in the proximal stomach, and are unlikely to perforate.[107] Bleeding from SRMD occurs from superficial mucosal capillaries, whereas bleeding associated with chronic PUD usually results from a single vessel.[107]

The mortality rate associated with clinically important SRMB is approximately 50% and is related to the underlying severity of disease and comorbidities in this patient population.[105,107,109] In contrast, the mortality associated with chronic PUD-related bleeding is approximately 10% but can increase dramatically in select patient populations.[103,110,111] Although the initial management of acute upper GI bleeding focuses on aggressive resuscitative measures and ensuring hemodynamic stability, the medical management of PUD-related bleeding and SRMB is distinctly different.[102,103,106,107]

PEPTIC ULCER-RELATED BLEEDING

The most common presenting signs and symptoms of PUD-related bleeding are hematemasis (vomiting up blood) or melena (dark, tarry stools) or possibly both. When evaluating patients with PUD-related bleeding, the degree of risk for adverse outcomes must be rapidly assessed in order to determine if the patient's condition constitutes a medical emergency.[102,103] Two risk-stratification tools exist for early assessment and triage.[112,113] The Blatchford score is a newer risk-stratification scale and is used to evaluate the need for urgent endoscopic intervention for patients presenting with PUD-related bleeding.[112] The scale values range from 0 to 23, with higher scores indicating higher risk. The most well-known scale, however, is the Rockall Score.[113] This validated risk-assessment instrument is composed of two assessments: the clinical score, which is performed prior to endoscopy, and the endoscopic score. The use of these risk-stratification tools can reduce the requirement of endoscopic procedures and lead to early discharge for low-risk patients while ensuring rapid intervention for patients at higher risk.[102] These data will also allow the pharmacist to make appropriate pharmacotherapy decisions based on the patient's assessed level of risk. When considering the risk of death due to PUD-bleeding, the following patients generally have poorer prognoses and usually require more aggressive intervention including admission to an intensive care unit (ICU).[102,103,106,107]

- Older than 60 years of age
- Comorbid conditions (e.g., ischemic heart disease, congestive heart failure, renal failure, hepatic failure, metastatic cancer)
- High transfusion requirements
- Ongoing blood loss
- Presence of hypovolemic shock (i.e. tachycardia with a pulse of ≥100 beats per minute, hypotension with a systolic blood pressure of <100 mmHg with concomitant orthostatic changes, such as an increase in the heart rate of ≥20 beats per minute or decrease in systolic blood pressure of ≥20 mmHg upon standing from a sitting position)
- Prolonged prothrombin time [or increased international normalized ratio (INR)]
- Erratic mental status

Initial therapy for patients with defined hemostatic instability should focus on correcting fluid volume loss though appropriate volume resuscitative measures. This is usually accomplished with a continuous 0.9% sodium chloride infusion (or blood products if clinically indicated) through two large bore peripheral intravenous catheters (i.e., 16 to 18 gauge).[102,104] The use of nasogastric (NG) tubes remains controversial but may aid in early assessment and gastric lavage.[102]

Diagnostic endoscopy is usually performed as early as possible (preferably within 24 hours of presentation) to identify the source of the bleeding, assess the potential risk for rebleeding, and, if appropriate, employ therapeutic interventions to promote hemostasis.[102,104] Several endoscopic treatment approaches (e.g., thermocoagulation, laser therapy, injection sclerotherapy, hemoclipping, and ligation) can be used; however, to maximize the likelihood of positive outcomes, patients are usually treated with a combination of thermocoagulation and injection of lesions with epinephrine.[102–104] The appearance of the ulcer at the time of endoscopy is a prognostic indicator for the risk of rebleeding.[102,104,110] Clean-based and flat spot (pigmented) ulcers are most commonly seen and are associated with a low risk of rebleeding (5% and 10%, respectively).[104,110] In most cases, patients with clean base ulcers can be immediately discharged after endoscopy on antiulcer therapy (usually twice daily PPI), while patients with flat spot ulcers may be admitted to the general hospital ward for a brief observation period. Patients with an adherent clot overlying the ulcer base are at intermediate risk of rebleeding (22%), and controversy exists as to the appropriate management of these patients.[104,110] Adherent clots can be removed, and then the lesion be reclassified based on what is observed following clot removal.[104,110] Patients with a visible vessel or active bleeding are at the highest risk of rebleeding (43% and 55%, respectively) and should be managed within an ICU for at least 24 hours and then monitored on a general medical/surgical service for an additional 48 hours (total of 72 hours), as rebleeding significantly increases mortality.[102,103,110]

8 Antisecretory therapy is often used as adjuvant therapy to endoscopic procedures to prevent PUD rebleeding in high-risk patients because acid impairs clot stability.[102] However, endoscopic hemostatis techniques remain the treatment of choice for patients with life-threatening bleeding, as this has been associated with better outcomes when compared with either placebo or pharmacotherapy alone.[102–104,109] H_2-Receptor antagonists are ineffective in preventing PUD rebleeding because they do not achieve an intragastric pH of 6 (which is needed to promote hemostatis and clot stability) and tolerance to their antisecretory effect develops rapidly (especially with high dose or intravenous therapy).[102–104,108,114,115] In contrast, PPIs reduce the incidence of rebleeding and need for surgery but have no significant impact on overall mortality.[102,103,114,115] Interestingly, subgroup analysis from two differing metaanalyses has suggested a mortality benefit with high-dose intravenous PPIs in a subpopulation of patients with the highest risk of rebleeding (i.e., nonbleeding visible vessel or active bleeding).[114,116]

The precise route (oral or intravenous) and the dose of PPI should be based on the clinical situation, risk of rebleeding, endoscopic identification of the lesion, and patient risk.[114,115] Because of the theoretical goal of maintaining intragastric pH values >6, and data from randomized, controlled trials, practice guidelines recommend that high-dose continuous infusion PPI (equivalent to omeprazole 80 mg given intravenously as a loading dose, followed by 8 mg/h continuous infusion for 72 hours) be used to reduce the risk of rebleeding in high-risk patients who have undergone

endoscopy hemostasis.[102,103,114,115] Because intravenous omeprazole is not available in the United States and three small randomized, controlled trials have not demonstrated any evidence of improved outcomes between the available intravenous PPIs and omeprazole, most clinicians consider intravenous pantoprazole and esomprazole to be equivalent to intravenous omeprazole on a milligram-per-milligram basis. Thus, intravenous pantoprazole and esomeprazole can be interchanged as there is currently no evidence to suggest that one PPI is superior to another.[115,117] The administration of high-dose continuous-infusion PPIs given prior to endoscopy hastens resolution of bleeding stigmata.[118] However, PPI therapy is not a replacement for interventional endoscopy for patients who are at high risk of rebleeding, as data demonstrate that the combination of a high-dose PPI continuous intravenous infusion with therapeutic endoscopy is superior to either strategy alone.[115,119] High-dose oral PPI therapy (omeprazole 80 mg/day for 5 days) is also effective; however, concerns exist as to whether critically ill patients will absorb the medication.[109,114] The risk of rebleeding is greatest within the first 72 hours (especially the first 24 hours), and it is during this time that antisecretory therapy to prevent rebleeding in high-risk patients should be employed.[102,103] Patients should be transitioned to an oral PPI upon completion of intravenous therapy. Somatostatin or octreotide have not demonstrated any significant benefit in treating nonvariceal bleeding and are not recommended at this time.[102,103]

Patients with upper GI bleeding should be tested for *H. pylori* at the time of endoscopy (see Tests for *Helicobacter Pylori*). However, the tests are associated with an increased rate of false-negatives when obtained during acute bleeding episodes.[120] If the initial results of the rapid urease test and/or histology are negative, a confirmatory test (^{14}C-urea breath test or serology) should be performed following the acute bleeding episode. There is no rationale for using intravenous therapy to eradicate *H. pylori*. Ulcer treatment, including *H. pylori* eradication, if appropriate, should be initiated after the acute bleeding episode has resolved (see Treatment of *Helicobacter Pylori*–Associated Ulcers and Treatment of NSAID-Induced Ulcers).

STRESS-RELATED MUCOSAL BLEEDING

Critically ill patients may develop SRMD leading to SRMB because of the homeostatic compromise that is associated with severe illness.[106,107] More than 75% (some studies suggesting up to 100%) of critically ill patients develop SRMD within the first 1 to 3 days of admission to an ICU, but the incidence of clinically important SRMB (defined as overt bleeding with concomitant hemodynamic instability and likely requirement for blood products) is 1% to 4%.[106,107,121] Clinically important bleeding increases the length of ICU stay by up to 11 days, results in excessive healthcare costs and is associated with increased mortality.[106,107,122] Thus, attempts to prevent SRMB are warranted in high-risk patients. Prophylactic therapy to prevent bleeding is most effective if initiated early in the patient's course.

9 Patients who are at risk for SRMB include those with respiratory failure (need for mechanical ventilation for longer than 48 hours), coagulopathy (INR >1.5, platelet count <50,000 mm^3), hypotension, sepsis, hepatic failure, acute renal failure, high-dose corticosteroid therapy (>250 mg/day hydrocortisone or equivalent), multiple trauma, severe burns (>35% of body surface area), head injury, traumatic spinal cord injury, major surgery, prolonged ICU admission (>7 days), or history of GI bleeding.[105–107,122] The relative importance of the various risk factors remains controversial, but most clinicians concur that patients with respiratory failure or coagulopathy should receive prophylaxis, as these two factors are independent risk factors for SRMB.[105,106] In the absence of these risk factors, some clinicians only administer prophylaxis to patients who have two of the aforementioned risk factors.[105] Since not all patients in a hospital or ICU are at increased risk of SRMB, a cost-effective approach should be developed to target prophylactic therapy at high-risk patients.

CLINICAL CONTROVERSY

Some clinicians feel that stress-related mucosal bleeding prophylaxis is indicated for all critically ill patients given the associated mortality and increased length of stay for patients who develop this complication. Others adhere to clinical guidelines that suggest only high-risk patients such as those with respiratory failure requiring ventilation or patients with coagulopathy and perhaps those patients with two or more other risk factors will benefit from prophylaxis.

Prevention of SRMB includes resuscitative measures that restore mucosal blood and pharmacotherapy that either maintains an intragastric pH of >4 or provides gastric mucosal protection.[105–107] Although the benefits of enteral nutrition to patient outcome (e.g., improved nutritional status enhances mucosal integrity) are of overall clinical importance, its precise role as a sole modality to prevent SRMB remains controversial.[106–107] Therapeutic options for the prevention of SRMB include antacids (which are of historical interest, as they are no longer used because of cumbersome dosage schedules and side effects), antisecretory drugs (H_2RAs and PPIs), and sucralfate (mucosal protectant).[105–107,109,122]

Antisecretory therapy is generally preferred for SRMB prophylaxis for several reasons. First, a large landmark study demonstrated that intravenous ranitidine was superior to oral sucralfate in preventing SRMB.[123] Second, ranitidine did not increase the risk for nosocomial pneumonia, as the incidence of pneumonia was not different between the two treatment groups.[123] Third, although sucralfate is an evidence based option, it is cumbersome, requiring multiple daily dosage administration (up to 4 times daily), which may occlude nasogastric tubes, cause constipation, interact with several medications, and/or increase the potential for aluminum toxicity in patients with renal dysfunction. Finally, sucralfate does not have any appreciable effect on reducing intragastric pH. Although data published in 2004 indicated that H_2RAs were the most commonly prescribed antisecretory agents used to prevent SRMB,[124] it is now estimated that PPIs have become the mainstay of therapy.[106] Regardless, numerous studies and years of experience support the use of H_2RAs, and they remain a recommended option for the prevention of SRMB.[105–107,124]

Parenteral H_2RAs may be administered as either continuous infusions or intermittent bolus doses (see Table 40–14). Cimetidine, given as a continuous intravenous infusion, is the only FDA-labeled H_2RA for the prevention of SRMB. Despite evidence suggesting that continuous infusions of the H_2RAs are superior to intermittent dosing at maintaining an intragastric pH >4, there is no evidence to suggest better outcomes with respect to prevention of SRMB.[106] Thus, intermittent bolus doses of H_2RAs are used more commonly than continuous infusions.[107,109] Drug interactions are more common with cimetidine, and for this reason the other H_2RAs (famotidine, ranitidine) are used more frequently.[106] Adverse events associated with the use of H_2RAs for the critically ill patient include thrombocytopenia, mental status changes (more common in older patients or individuals with renal or hepatic compromise), and tachyphylaxis (especially with parenteral or high dose therapy).[106] Given that the H_2RAs are renally eliminates, dosage reductions are recommended for patients with renal dysfunction.

TABLE 40-14 Pharmacotherapy Options for Prophylaxis of Stress-Related Mucosal Bleeding

Drug and Route	Dosage
Parenteral H_2RAs	
Cimetidine	300 mg IV loading dose followed by a 50 mg/h as a continuous infusion[a] or 300 mg IV every 6 to 8 hours
Ranitidine	6.25 mg/h as a continuous infusion or 50 mg IV every 6 to 8 hours
Famotidine	1.7 mg/h as a continuous infusion or 20 mg IV every 12 hours
Oral/NG PPIs	
Omeprazole	20–40 mg orally/NG[b] every 12 to 24 hours
Omeprazole/ bicarbonate powder for oral suspension	40 mg orally/NG to start, then followed by an additional 40 mg in 6 to 8 hours as a loading dose, and then 40mg every 24 hours
Lansoprazole	30 mg orally/NG[b,c] every 12 to 24 hours
Pantoprazole	40 mg orally/NG[b] every 12 to 24 hours
Parenteral PPIs	
Pantoprazole	40-80 mg IV every 12 to 24 hours
Esomprazole	40 mg IV every 12 to 24 hours

H_2RA, histamine-$_2$ receptor antagonist; PPI, proton pump inhibitor; IV, intravenous; NG, nasogastric tube.
[a]Product is FDA approved for the prevention of stress-related mucosal bleeding.
[b]Administered as an extemporaneously compounded suspension made with sodium bicarbonate.
[c]Administered as a rapidly disintegrating tablet given orally or by NG dissolved in 10 mL of water.

The PPIs are more potent than H_2RAs in inhibiting acid secretion and, unlike H_2RAs, tolerance does not develop.[106,107,109,122] Although there are limited data assessing the efficacy of PPIs for the prevention of SRMB, recent reports suggest that PPIs may be used as alternatives to H_2RAs or sucralfate.[122,125,126] Initial open-label studies of PPIs for SRMB prophylaxis were performed with omeprazole compounded suspensions given as 40 mg for two doses on the first day, followed by 20 mg/day thereafter in critically ill or trauma patients requiring mechanical ventilation and the presence of at least one additional risk factor.[127,128] The results of these studies demonstrated significant pH control above 4 and no GI bleeding in either trial. Because of the small number of subjects, no firm clinical outcomes can be derived from these studies. Since then, numerous extemporaneously compounded sodium bicarbonate suspensions of PPIs (see Table 40–11) have been used as cost-effective regimens for stress ulcer prophylaxis in patients with NG tubes.[106,109,122,129] In one study, immediate-release omeprazole–sodium bicarbonate suspension (40 mg × 2 doses, then 40 mg/day) was more effective than continuous infusion cimetidine in maintaining intragastric pH >4 in critically ill patients, but there was no difference in the incidence of clinically important SRMD between the two groups.[125] Based on meeting the prespecified criteria for noninferiority, immediate-release omeprazole gained FDA labeling for the prevention of SRMB.[125] In another trial of ICU patients requiring mechanical ventilation, patients were randomized to receive either lansoprazole 30 mg given as a rapidly disintegrating tablet mixed in 10 mL of water and administered via an NG tube or lansoprazole 30 mg given as an intravenous infusion (no longer available in the United Satates) once daily for 72 hours.[130] Enterally administered lansoprazole, despite having a lower bioavailability, resulted in superior intragastric pH control when compared with the intravenously administered lansoprazole.

One of the most compelling dose-finding pilot studies to evaluate the use of intravenous PPIs for SRMB prophylaxis was performed in over 200 ICU patients examining five different dosing strategies of pantoprazole (40 mg given every 8 hours, every 12 hours, and every 24 hours or 80 mg given every 12 hours or every 24 hours) versus cimitidine given as a 300 mg intravenous bolus followed by a 50 mg/h continuous infusion.[126] Each regimen was given for at least 48 hours and for up to 7 days. The time the intragastric pH was ≥4 increased from day 1 to day 2 in all the pantoprazole groups, whereas it actually decreased in the cimetidine group suggesting tachyphylaxis. No bleeding was identified in any of the treatment groups. The results suggest appropriate pH control can be obtained with doses of 80 mg given on day 1 and 40 mg given every 12 hours thereafter. The use of intravenous esomeprazole has also demonstrated efficacy in a small number of clinical studies.[106] Given the relatively limited data, the overall efficacy, optimal dosage, frequency, and route of administration for PPIs in the prevention of SRMB remains to be fully elucidated.[106,107] Based on the available evidence, several PPI dosing regimens for SRMB prophylaxis exist (see Table 40–14). Adverse events that have been described when the PPIs are used for this indication include an increased risk of enteric infections, including *C. difficile* associated diarrhea and noscomial pneumonia.[106]

10 When deciding on the most appropriate pharmacotherapy plan for the prevention of SRMB for a specific patient, the clinical presentation of the patient and medication costs should be used as a guide. Patients who can take oral medication or have a working NG tube in place may be placed on an oral or compounded PPI suspension as a cost-effective measure. For most patients who are not able to utilize one of these routes, an intravenous H_2RA is appropriate. However, if the patient has renal dysfunction, develops thrombocytopenia, or mental status changes while on an H_2RA, then an intravenous PPI may be the most appropriate prophylaxis option. Consideration should be given to both the patient's clinical condition as well as the most cost effective option when developing protocols for preventing SRMB.

Improvement in the patient's overall medical condition (resolution of risk factors, discharge from the ICU, extubation, and oral intake) suggests that prophylactic therapy can be discontinued.[106] Too often the patient is continued on SRMB prophylaxis upon transition to the general medical/surgical unit and is often discharged on oral PPI therapy without an appropriate indication.[131] This results in unnecessary costs for the patient and the healthcare system.[131] Pharmacists should identify patients in which SRMB prophylaxis is no longer indicated.[106] If a patient develops clinically important bleeding, endoscopic evaluation of the GI tract is indicated along with aggressive antisecretory therapy (see the section Peptic Ulcer-Related Bleeding).

ABBREVIATIONS

BAO: basal acid output
COX-1: cyclooxygenase-1
COX-2: cyclooxygenase-2
CYP450: cytochrome P450
ECL: enterochromaffin-like
ELISA: enzyme-linked immunosorbent assay
GERD: gastroesophageal reflux disease
H. pylori: *Helicobacter pylori*
H_2RA: histamine-2 receptor antagonist
ICU: intensive care unit
MALT: mucosa-associated lymphoid tissue
MAO: maximal acid output
MEN: multiple endocrine neoplasia
NSAID: nonsteroidal antiinflammatory drug
NG: nasogastric
NUD: nonulcer dyspepsia
PG: prostaglandin
PPI: proton pump inhibitor

PUD: peptic ulcer disease

SRMB: stress-related mucosal bleeding

SRMD: stress-related mucosal damage

UBT: urea breath test

ZES: Zollinger-Ellison syndrome

CHAPTER 41

Inflammatory Bowel Disease

BRIAN A. HEMSTREET

KEY CONCEPTS

1. The exact cause of inflammatory bowel disease (IBD) is unknown, although there are components that appear to be infectious and other components that suggest immune dysregulation. Genetic variations explain some of the increased risk of disease occurrence.
2. Ulcerative colitis (UC) is confined to the rectum and colon, causes continuous lesions, and affects primarily the mucosa and the submucosa. Crohn's disease (CD) can involve any part of the gastrointestinal (GI) tract, often causes discontinuous (skip) lesions, and is a transmural process that can result in fistulas, perforations, or strictures.
3. Common GI complications of IBD include rectal fissures, fistulas (CD), perirectal abscess (UC), and colon cancer, while possible extraintestinal manifestations include hepatobiliary complications, arthritis, uveitis, skin lesions (including erythema nodosum and pyoderma gangrenosum), and aphthous ulcerations of the mouth.
4. The severity of UC may be assessed by stool frequency, presence of blood in stool, fever, pulse, hemoglobin, erythrocyte sedimentation rate, C-reactive protein, abdominal tenderness, and radiologic or endoscopic findings. The severity of CD can be assessed using similar parameters, in addition to the CD activity index, which includes stool frequency, presence of blood in stool, endoscopic appearance, and physician's global assessment.
5. The goals of IBD treatment are resolution of acute inflammation and complications, alleviation of systemic manifestations, maintenance of remission, and for some patients surgical palliation or cure.
6. The first line of treatment for mild to moderate UC or Crohn's colitis consists of oral aminosalicylates, such as sulfasalazine or mesalamine; mesalamine or steroid enemas or suppositories may be used for distal disease. Certain delayed-release oral formulations of mesalamine may be used for Crohn's ileitis. Controlled-release budesonide may be used for CD confined to the ileum and/or ascending colon.
7. Corticosteroids are often required for acute UC or CD. The duration of steroid use should be minimized and the dose tapered gradually over 3 to 4 weeks.
8. Infliximab is a treatment option for patients with moderate to severe active UC and for those patients with UC who are dependent on corticosteroids. Azathioprine or mercaptopurine may be used for maintenance of remission as an alternative to infliximab for patients with UC who have failed aminosalicylates and for patients who are corticosteroid dependent.
9. Intravenous continuous infusion of cyclosporine may be effective in treating severe colitis that is refractory to corticosteroids as an option to delay or prevent the need for surgery.
10. Sulfasalazine and mesalamine derivatives can prevent recurrence of acute disease in many patients, while steroids are ineffective for this purpose.
11. Other drugs that are useful for treatment of CD include infliximab, adalimumab, and certolizumab (for moderate to severe or fistulizing disease); methotrexate, azathioprine, or mercaptopurine (for inadequate response or to reduce steroid dosage); metronidazole (for perineal disease); and cyclosporine (for refractory disease).

There are two forms of idiopathic IBD: (1) UC, a mucosal inflammatory condition confined to the rectum and colon, and (2) CD, a transmural inflammation of the GI tract that can affect any part, from the mouth to the anus. The etiologies of both conditions are unknown, but they may have some common pathogenic mechanisms.

EPIDEMIOLOGY

Inflammatory bowel disease (IBD) is most prevalent in Western countries and in areas of northern latitude.[1] The reported rates of IBD are highest in Scandinavia, Great Britain, and North America.[2] Crohn's disease (CD) has an incidence of 3.6 to 8.8 per 100,000 persons in the United States and a prevalence of 20 to 40 per 100,000 people.[1–3] The incidence of CD varies considerably among studies, but has clearly increased dramatically over the last 3 or 4 decades.[3,4] Ulcerative colitis (UC) incidence ranges from 3 to 15 cases per 100,000 persons per year among the white population with a prevalence of 80 to 120 per 100,000.[4] The incidence of UC has remained relatively constant over many years.[2] Although most epidemiologic studies combine ulcerative proctitis with UC, 17% to 49% of cases are classified as proctitis.

Both sexes are affected equally with IBD, although some studies show slightly greater numbers of women with CD and males with UC.[2] UC and CD have bimodal distributions in age of initial

presentation. The peak incidence occurs in the second or third decades of life, with a second peak occurring between 60 and 80 years of age.[1,2] A high incidence of UC (4 to 5 times normal) occurs in Ashkenazi Jews, while blacks and Asians have a relatively low incidence of occurrence.[2,5,6]

ETIOLOGY

1 Although the exact etiology of UC and CD is unknown, similar factors are believed responsible for both conditions (Table 41–1). The major theories of the cause of IBD involve a combination of infectious, genetic, and immunologic factors.[7] The inflammatory response with IBD may indicate abnormal regulation of the normal immune response or an autoimmune reaction to self-antigens. The microflora of the gastrointestinal tract may provide an environmental trigger to activate inflammation.[8] CD has been described as a disorder mediated by T lymphocytes that arise in genetically susceptible individuals as a result of a breakdown in the regulatory constraints on mucosal immune responses to enteric bacteria.[9]

INFECTIOUS FACTORS

Microorganisms are a likely factor in the initiation of inflammation in IBD.[8] However, no definitive infectious cause of IBD has been found, even though the presentation is similar to that caused by some invasive microbial pathogens. Patients with IBDs have increased numbers of surface-adherent and intracellular bacteria.[10] IBD may involve a loss of tolerance toward normal bacterial flora.[11] Other supporting evidence for an infectious etiology is that colitis does not appear to occur in genetically altered germ-free animals, intestinal lesions in IBD typically predominate in areas of highest bacterial exposure, and observed differences in the existing makeup of the resident luminal and muscosal bacterial flora in healthy subjects versus those with IBD.[8]

Suspect infectious agents include the measles virus, protozoans, mycobacteria such as *Mycobacterium paratuberculosis* or *avium*, and other bacteria such as *Listeria monocytogenes*, *Chlamydia trachomatis*, and *Escherichia coli*.[3,12] *Clostridium difficile* infection may lead to increases in frequency of relapses and enhanced severity of IBD.[3] Also, certain strains of bacteria produce toxins (necrotoxins, hemolysins, and enterotoxins) that cause mucosal damage. Bacteria elaborate peptides (e.g., formyl-methionyl-leucyl-phenylalanine) that have chemotactic properties and that cause an influx of inflammatory cells with subsequent release of inflammatory mediators and tissue destruction. Microbes may elaborate superantigens, which are capable of global T-lymphocyte stimulation and subsequent inflammatory response.[13] As many as 60% of patients with CD have circulating antibody to *Saccharomyces cerevisiae*, but this may not represent a disease mechanism.[9]

GENETIC FACTORS

Genetic factors predispose patients to IBDs, particularly CD. In studies of monozygotic twins, there has been a high concordance rate, with both individuals of the pair having an IBD (particularly CD).[9] Also, first-degree relatives of patients with IBD may have up to a 20-fold increase in the risk of disease.[10] Several genetic markers have been identified that occur more frequently for patients with IBD. The CARD15 gene on chromosome 16, formerly referred to as NOD2, is thought to account for 20% of the genetic predisposition to CD. Likewise, polymorphisms of the interleukin 23 receptor (IL23R) are strongly associated with CD and possibly UC.[15–17] Human leukocyte antigen (HLA) DR2 has been associated with UC in Japanese subjects, while HLA DR3 has been associated with UC in European subjects.[12,14] Additionally the multidrug resistance gene 1 (ABCB/MDR 1) on chromosome 7 has been identified as a potential susceptibility gene for UC.[15] As methods for identifying genetic variations have advanced, many other genes and single nucleotide polymorphisms have been associated with IBD, including DLG5, OCTN1, LC22A4, and CARD4, among others.[12,14,16,17] This represents an intense area of research focus as identifying means to alter or prevent the disease process.

IMMUNOLOGIC MECHANISMS

The immune system is known to play a critical role in the underlying pathogenesis of IBD. In CD the bowel wall is infiltrated with lymphocytes, plasma cells, mast cells, macrophages, and neutrophils. Similar infiltration has been observed in the mucosal layer of the colon in patients with UC. Inflammation in IBD is maintained by an influx of leukocytes from the vascular system into sites of active disease. This influx is promoted by expression of adhesion molecules (such as α_4 integrins) on the surface of endothelial cells in the microvasculature in the area of inflammation.[11,18] Many of the systemic manifestations of IBD have an immunologic etiology (e.g., arthritis or uveitis). Finally, IBD is typically responsive to immunosuppressive drugs (e.g., corticosteroids and azathioprine).

The immune theory of IBD assumes that IBD is caused by an inappropriate reaction of the immune system. Potential immunologic mechanisms include both autoimmune and nonautoimmune phenomena.[10,17] Autoimmunity may be directed against mucosal epithelial cells or against neutrophil cytoplasmic elements. Some patients with IBD have abnormal structural features of colonic epithelial cells even in the absence of active disease. Autoantibodies to these structures have been reported. Also, antineutrophil cytoplasmic antibodies are found in a high percentage of patients with UC (70%) and much less frequently with CD.[10] Presence of antineutrophil cytoplasmic antibodies in left-sided UC is associated with resistance to medical therapy.[19] Dysregulation of cytokines is a component of IBD. Specifically, Th_1 cytokine activity (which enhances cell-mediated immunity and suppresses humoral immunity) is excessive with CD, whereas Th_2 cytokine activity (which inhibits cell-mediated immunity and enhances humoral immunity) is excessive with UC.[17,20] The result is that patients have inappropriate T-cell responses to antigens from their own intestinal microflora.[17,20] The IL23 pathway has also been implicated in clonal expansion of Th_{17} cells, which produce various proinflammatory cytokines.[17] Expression of interferon-γ (a Th_1 derived cytokine)

in intestinal mucosa of diseased patients is increased, while IL-4 (a Th2-derived cytokine) is reduced.[7,21]

Tumor necrosis factor-α (TNF-α) is a pivotal proinflammatory cytokine in both CD and UC. TNF-α can recruit inflammatory cells to inflamed tissues, activate coagulation, and promote the formation of granulomas. Production of TNF-α is increased in the mucosa and intestinal lumen of patients with CD.[7,10,21] Eicosanoids such as leukotriene B_4 are increased in rectal dialysates and tissues of IBD patients and are related to disease activity. Leukotriene B_4 enhances neutrophil adherence to vascular endothelium and acts as a neutrophil chemoattractant. These findings have led to the consideration of leukotriene inhibitor strategies for therapy.

PSYCHOLOGICAL FACTORS

Mental health changes appear to possibly correlate with remissions and exacerbations, especially of UC, but psychological factors overall are not thought to be an etiologic factor. There is a weak association between the number of stressful events experienced and the time to relapse of UC.[22,23]

DIET, SMOKING, AND NONSTEROIDAL ANTIINFLAMMATORY DRUG (NSAID) USE

Changes in diet by people in industrialized countries where CD is more common have not been consistently associated with the disease. Studies of increased intake of refined sugars or chemical food additives and reduced fiber intake have provided conflicting results regarding risk for CD. Smoking plays an important but contrasting role in UC and CD.

Smoking appears to be protective for UC.[10] The risk of developing UC in smokers is about 40% of that in nonsmokers.[2] Clinical relapses are associated with smoking cessation, and nicotine transdermal administration has been effective in improving symptoms for patients with UC.[24] In contrast, smoking is associated with a twofold increased frequency of CD.[2] Patients with CD who stop smoking have a more benign course than patients who continue smoking.[25] The mechanisms of these differing effects have not been identified.

Use of NSAIDs may trigger disease occurrence or lead to disease flares.[10,23,26] The effect of NSAIDs to inhibit prostaglandin production through cyclooxygenase inhibition may impair mucosal barrier protective mechanisms. The increased risk seems to be present for cyclooxygenase-2 inhibitors as well as cyclooxygenase-1 inhibitors; however, it is unclear whether cyclooxygenase-2 inhibitors may be somewhat safer in select patients with IBD.[27,28] The use of NSAIDs may be warranted in some patients with IBD, particularly those with concomitant arthritic symptoms, if the benefit is thought to outweigh the potential risk of disease flare.[23]

PATHOPHYSIOLOGY

UC and CD differ in two general respects: anatomic sites and depth of involvement within the bowel wall. There is, however, overlap between the two conditions, with a small fraction of patients showing features of both diseases. Confusion can occur, particularly when the inflammatory process is limited to the colon. Table 41–2 compares pathologic and clinical findings of the two diseases.

TABLE 41-2 Comparison of the Clinical and Pathologic Features of Crohn's Disease and Ulcerative Colitis

Feature	Crohn's Disease	Ulcerative Colitis
Clinical		
Malaise, fever	Common	Uncommon
Rectal bleeding	Common	Common
Abdominal tenderness	Common	May be present
Abdominal mass	Common	Absent
Abdominal pain	Common	Unusual
Abdominal wall and internal fistulas	Common	Absent
Distribution	Discontinuous	Continuous
Aphthous or linear ulcers	Common	Rare
Pathologic		
Rectal involvement	Rare	Common
Ileal involvement	Very common	Rare
Strictures	Common	Rare
Fistulas	Common	Rare
Transmural involvement	Common	Rare
Crypt abscesses	Rare	Very common
Granulomas	Common	Rare
Linear clefts	Common	Rare
Cobblestone appearance	Common	Absent

ULCERATIVE COLITIS

2 UC is confined to the rectum and colon and affects the mucosa and the submucosa. In some instances, a short segment of terminal ileum may be inflamed; this is referred to as *backwash ileitis.* Unlike CD, the deeper longitudinal muscular layers, serosa, and regional lymph nodes are not usually involved.[1,10,11] Fistulas, perforation, or obstruction are uncommon because inflammation is usually confined to the mucosa and submucosa.

The primary lesion of UC occurs in the crypts of the mucosa (crypts of Lieberkuhn) in the form of a crypt abscess. Here, frank necrosis of the epithelium occurs; it is usually visible only with microscopy but may be seen grossly when coalescence of ulcers occurs. Extension and coalescence ulcers may surround areas of uninvolved mucosa. These islands of mucosa are called *pseudopolyps.* Other typical ulceration patterns include a "collar-button ulcer," which results from extensive submucosal undermining at the ulcer edge.[10,29,30] The extensive mucosal damage seen in UC can result in significant diarrhea and bleeding, although a small percentage of patients experience constipation.

3 UC can be accompanied by complications that may be local (involving the colon or rectum) or systemic (not directly associated with the colon). With either type the complications may be mild, serious, or even life threatening. Local complications occur in the majority of UC patients. Other complications include hemorrhoids, anal fissures, or perirectal abscesses and are more likely to be present during active colitis. Enteroenteric fistulas are rare.

A major complication is toxic megacolon, which is a segmental or total colonic distension of greater than 6 cm with acute colitis and signs of systemic toxicity.[31] It is a severe condition that occurs in up to 7.9% of UC patients admitted to hospitals and results in death rates of up to 50%. With toxic megacolon, ulceration extends below the submucosa, sometimes even reaching the serosa. Vasculitis, swelling of the vascular endothelium, and thrombosis of small arteries occur; involvement of the muscularis propria causes loss of colonic tone, which leads to dilatation and potential perforation. The patient with toxic megacolon usually has a high fever, tachycardia, distended abdomen, and elevated white blood cell count, and a dilated colon is observed on x-ray.[7,31] Colonic perforation, however, may occur with or without toxic megacolon and is a greater risk with the first attack. Another infrequent major local complication is massive colonic hemorrhage. Colonic stricture, sometimes with clinical obstruction, may also complicate long-standing UC.

The risk of colonic carcinoma is much greater for patients with UC as compared with the general population and begins to increase

10 to 15 years after the diagnosis of UC. The absolute risk may be as high as 30% 35 years after diagnosis and as high as 49% for patients who have a long history of disease and who were less than 15 years of age at the time of diagnosis.

The inflammatory response seen in IBD has also been blamed for the systemic complications seen in both CD and UC. The systemic extraintestinal complications of UC are summarized in the next section.

Hepatobiliary Complications

Approximately 11% of patients with UC are reported to have hepatobiliary complications with overall frequencies ranging from 5% to 95% for patients with IBD.[32–35] Hepatic complications include fatty liver, pericholangitis, chronic active hepatitis, and cirrhosis. Biliary complications include primary sclerosing cholangitis, cholangiocarcinoma, and gallstones.

Fatty infiltration of the liver may be a result of malabsorption, protein-losing enteropathy, or concomitant steroid use. The most common hepatic complication is pericholangitis (acute inflammation surrounding the intrahepatic portal venules, bile ducts, and lymphatics), which occurs in up to one third of UC patients. This is associated with progressive fibrosis of intrahepatic and extrahepatic bile ducts in a small percentage of UC patients and is referred to as *primary sclerosing cholangitis*. Cirrhosis may be a sequela of cholangitis or of chronic active hepatitis. Often the severity of hepatic disease does not correlate with gastrointestinal disease activity.

Gallstones occur commonly for patients with CD (particularly with terminal ileal disease) and may be related to bile salt malabsorption. In addition, cholangiocarcinoma occurs 10 to 20 times more frequently in IBD patients as compared with the general population.[32]

Joint Complications

Arthritis commonly occurs in IBD patients and is typically asymmetric (unlike rheumatoid arthritis) and migratory, involving one or a few usually large joints.[32,34,35] The joints most often affected are the knees, hips, ankles, wrists, and elbows in decreasing frequency. Sacroiliitis also occurs commonly. Arthritis associated with UC is generally related to the severity of colonic disease, and resolution without recurrence is seen with proctocolectomy. In addition, arthritis in this setting is different from rheumatoid arthritis in that rheumatoid factors are generally not detected. It is nondeforming and nondestructive, even after multiple episodes.

Another potential joint complication is ankylosing spondylitis, which is often unresponsive to treatment. The incidence of ankylosing spondylitis in patients with UC is 30 times that of the general population and occurs most commonly for patients with the HLA-B27 phenotype.

Ocular Complications

Ocular complications including iritis, uveitis, episcleritis, and conjunctivitis occur in up to 10% of patients with IBD.[32,34,35] The most commonly reported symptoms with iritis and uveitis include blurred vision, eye pain, and photophobia. Episcleritis is associated with scleral injection, burning, and increased secretions. These complications may parallel the severity of intestinal disease, and recurrence after colectomy with UC is uncommon.

Dermatologic and Mucosal Complications

Skin and mucosal lesions associated with IBD include erythema nodosum, pyoderma gangrenosum, and aphthous ulceration. Five percent to 10% of IBD patients experience dermatologic or mucosal complications.[1,34,35]

Raised, red, tender nodules that vary in size from 1 cm to several centimeters are manifestations of erythema nodosum. They are typically found on the tibial surfaces of the legs and arms. These lesions are more commonly observed in CD patients and are noted to correlate with disease severity.

Pyoderma gangrenosum occurs more commonly for patients with UC (1% to 5% incidence) and is characterized by discrete skin ulcerations that have a necrotic center and a violaceous color of the surrounding skin.[34] They can be seen on any part of the body but are more commonly found on the lower extremities.

Oral lesions are found in 6% to 20% of patients with CD and 8% of patients with UC.[31] The most common lesion seen with CD is aphthous stomatitis. The severity of these lesions tends to parallel the disease course.

CROHN'S DISEASE

Crohn's disease is best characterized as a transmural inflammatory process. The terminal ileum is the most common site of the disorder, but it may occur in any part of the GI tract from mouth to anus. About two thirds of patients have some colonic involvement, and 15% to 25% of patients have only colonic disease.[10,13] Patients often have normal bowel separating segments of diseased bowel; that is, the disease is discontinuous.

Regardless of the site, bowel wall injury is extensive and the intestinal lumen is often narrowed. The mesentery first becomes thickened, edematous, and then fibrotic. Ulcers tend to be deep and elongated and extend along the longitudinal axis of the bowel, at least into the submucosa. The "cobblestone" appearance of the bowel wall results from deep mucosal ulceration intermingled with nodular submucosal thickening.

Complications of CD may involve the intestinal tract or organs unrelated to it. Small bowel stricture and subsequent obstruction is a complication that may require surgery. Fistula formation is common and occurs much more frequently than with UC.[12] Fistulas often occur in the areas of worst inflammation, where loops of bowel have become matted together by fibrous adhesions. Fistulas may connect a segment of the GI tract to skin (enterocutaneous fistula), two segments of the GI tract (enteroenteric fistula), or the intestinal tract with the bladder (enterovesicular fistula) or vagina. CD fistulae or abscesses associated with them frequently require surgical treatment.

Bleeding with CD is usually not as severe as with UC, although patients with CD may have hypochromic anemia. In addition, as with UC, the risk of carcinoma is increased but not as greatly as with UC.

Systemic complications of CD are common, and similar to those found with UC. Arthritis, iritis, skin lesions, and liver disease often accompany CD. Renal stones occur in up to 10% of patients with CD (less frequently with UC) and are caused by fat malabsorption, which allows for greater oxalate absorption and formation of calcium oxalate stones. Gallstones also occur with greater frequency in patients with ileitis, possibly because of bile acid malabsorption at the terminal ileum.

Nutritional deficiencies are common with CD.[36,37] Reported frequencies of various nutritional parameters are weight loss, 40% to 80%, up to 90% reported in children at the time of diagnosis; growth failure in children, 15% to 88%; iron deficiency anemia, 39%; vitamin B_{12} deficiency, 18.4%; folate deficiency, 19%; hypoalbuminemia, 17% to 76%; hypokalemia, 33%; and osteomalacia, 36%. There are usually decreased fat stores and lean tissue. Growth failure in children may also be associated with hypozincemia.

TABLE 41-3 Clinical Presentation of Ulcerative Colitis

Signs and symptoms
- Abdominal cramping
- Frequent bowel movements, often with blood in the stool
- Weight loss
- Fever and tachycardia in severe disease
- Blurred vision, eye pain, and photophobia with ocular involvement
- Arthritis
- Raised, red, tender nodules that vary in size from 1 cm to several centimeters

Physical examination
- Hemorrhoids, anal fissures, or perirectal abscesses may be present
- Iritis, uveitis, episcleritis, and conjunctivitis with ocular involvement
- Dermatologic findings with erythema nodosum, pyoderma gangrenosum, or aphthous ulceration

Laboratory tests
- Decreased hematocrit/hemoglobin
- Increased ESR or CRP
- Leukocytosis and hypoalbuminemia with severe disease
- (+) perinuclear antineutrophil cytoplasmic antibodies

CLINICAL PRESENTATION

The patterns of clinical presentation of IBD can vary widely. Patients may have a single acute episode that resolves and does not recur, but most patients experience acute exacerbations after periods of remission. With more severe disease, prolonged illness may occur.

ULCERATIVE COLITIS

Although a typical clinical picture of UC can be described, there is a wide range of presentation, from mild abdominal cramping with frequent small-volume bowel movements to profuse diarrhea (Table 41–3). Most patients with UC experience intermittent bouts of illness after varying intervals with no symptoms. Only a small percentage of patients has continuous unremitting symptoms or a single acute attack with no subsequent symptoms.

4 Complex disease classifications are generally not used in clinical practice for UC. The arbitrarily determined distinctions of mild, moderate, and severe disease activity are generally used, and these are determined largely by clinical signs and symptoms.[38,39]

Mild: Fewer than 4 stools daily, with or without blood, with no systemic disturbance and a normal erythrocyte sedimentation rate (ESR).

Moderate: More than 4 stools per day but with minimal systemic disturbance.

Severe: More than 6 stools per day with blood, with evidence of systemic disturbance as shown by fever, tachycardia, anemia, or ESR of greater than 30 mm/h.

Fulminant: More than 10 bowel movements per day with continuous bleeding, toxicity, abdominal tenderness, requirement for transfusion, and colonic dilation.

It is also important to determine disease extent; that is, which part of the colon is involved—rectum, descending colon only, or the entire colon. Patients with "distal" disease have inflammation limited to areas distal to the splenic flexure (also referred to as *left-sided* disease), while those with "extensive disease" have inflammation extending proximal to the splenic flexure.[38,39] Likewise, inflammation confined to the rectal area is referred to as *proctitis*, while disease involving the rectum and sigmoid colon is referred to as *proctosigmoiditis*.[29] Inflammation of the majority of the colon is deemed *pancolitis*.

Two thirds of patients with UC have mild disease, which almost always starts in the rectum. Systemic signs and symptoms of the disease (e.g., arthritis, uveitis, or pyoderma gangrenosum) may be present in these patients and, in fact, may be the reason the patient seeks medical attention. Patients with mild disease are believed to be at lower risk of colon cancer. Moderate disease is observed in one fourth of patients.

With severe disease, the patient is usually found to be in acute distress, has profuse bloody diarrhea, and often has a high fever with leukocytosis and hypoalbuminemia. Often, the patient is dehydrated and therefore may be tachycardic and hypotensive. This presentation may have a sudden onset with rapid progression.

The diagnosis of UC is made on clinical suspicion and confirmed by biopsy, stool examinations, sigmoidoscopy or colonoscopy, or barium radiographic contrast studies. The presence of extracolonic manifestations such as arthritis, uveitis, and pyoderma gangrenosum may also aid in establishing the diagnosis.[38]

CROHN'S DISEASE

As with UC, the presentation of CD is highly variable. A single episode may not be followed by further episodes, or the patient may experience continuous, unremitting disease. The time between the onset of complaints and the initial diagnosis may be as long as 3 years. The patient typically presents with diarrhea and abdominal pain. Hematochezia occurs in about one half of the patients with colonic involvement and much less frequently when there is no colonic involvement. Commonly, a patient may first present with a perirectal or perianal lesion (Table 41–4). The diagnosis should also be suspected in children with growth retardation, especially with abdominal complaints.

Much like UC, guidelines classify the severity of active CD by the presence of several signs and symptoms.[40] Patients with mild to moderate CD are typically ambulatory and have no evidence of dehydration, systemic toxicity, loss of body weight, or abdominal tenderness, mass, or obstruction. Moderate to severe disease is considered for patients who fail to respond to treatment for mild to moderate disease or those with fever, weight loss, abdominal pain or tenderness, vomiting, intestinal obstruction, or significant anemia. Severe to fulminant CD is classified as the presence of persistent symptoms or evidence of systemic toxicity despite corticosteroid or biologic treatment or presence of cachexia, rebound tenderness, intestinal obstruction, or abscess. Disease activity may be assessed and correlated by evaluation serum C-reactive protein (CRP) concentrations.

The course of CD is characterized by periods of remission and exacerbation. Some patients may be free of symptoms for years, while others experience chronic problems in spite of medical therapy. As with UC, the diagnosis of CD involves a thorough evaluation using laboratory, endoscopic, and radiologic testing to detect the extent and characteristic features of the disease. Because of similarities that may exist between UC and CD confined to

TABLE 41-4 Clinical Presentation of Crohn's Disease

Signs and symptoms
- Malaise and fever
- Abdominal pain
- Frequent bowel movements
- Hemotachezia

the colon, a definitive diagnosis cannot be made in up to 15% of cases, even with pathologic specimens in hand. These patients may be referred to as *indeterminate colitis*. Small bowel involvement, strictures detected on radiographs, and presence of fistulas are characteristic of CD.

TREATMENT

Inflammatory Bowel Disease

DESIRED OUTCOME

5 To treat IBD properly, the clinician must have a clear concept of realistic therapeutic goals for each patient. These goals may relate to resolution of acute inflammatory processes, resolution of attendant complications (e.g., fistulas and abscesses), alleviation of systemic manifestations (e.g., arthritis), maintenance of remission from acute inflammation, or surgical palliation or cure. Treatment goals and the approach to the therapeutic regimen differ considerably between UC and CD.

When determining goals of therapy and selecting therapeutic regimens, it is important to understand the natural history of IBD.[40] Some cases of acute UC are self-limited. With mild to moderate acute colitis without systemic symptoms, 20% of patients may experience spontaneous improvement in their disease within a few weeks; however, a small percentage of patients may go on to experience more serious disease. With severe colitis, improvement without treatment cannot be expected. For instance, the response to medical management of toxic megacolon is variable and emergent colectomy may be required. When remission of UC is achieved, it is likely to last at least 1 year with medical therapy. In the absence of medical therapy, one half to two thirds of patients are likely to relapse within 9 months.[39] In some reports, remission rates with placebo have approached those found with active treatment.

Since CD is typified by a chronic relapsing course, approximately 20% of patients with CD will experience a relapse annually.[40] The chance of sustained remission is impacted by response to treatment. If patients remain in remission for 1 year, they have an 80% chance of remaining in remission the subsequent year, while 70% of patients will continue to have active disease in the year following a 12-month period in which they had active disease.[40] Thus inducing and maintaining remission for patients with IBD is an important aspect of treatment.

GENERAL APPROACH TO TREATMENT

6 Treatment of IBD centers on agents used to relieve the inflammatory process. Aminosalicylates, corticosteroids, antimicrobials, immunosuppressive agents, such as azathioprine, mercaptopurine, and methotrexate, and biologic agents are commonly used to treat active disease and for some agents to lengthen the time of disease remission. Information regarding the extent and distribution of the disease should be taken into account, as this will often dictate the route and formulation of drug therapy that will be most effective.

In addition to the use of drugs, surgical procedures are sometimes performed when active disease is inadequately controlled or when the required drug dosages pose an unacceptable risk of adverse effects. For most patients with IBD, nutritional considerations are also important because these patients are often malnourished. Finally, a variety of therapies may be used to address complications or symptoms of IBD. For example, antidiarrheals may be used in some patients with relatively well-controlled disease, although these are generally to be avoided in active moderate to severe UC because they may contribute to the development of toxic colonic dilatation. Antimicrobial agents may be used in conjunction with drainage when abscesses are present or for patients with perianal disease. Iron supplementation may be required, particularly with UC, where blood loss from the colon can be significant.

NONPHARMACOLOGIC THERAPY

Nutritional Support

Proper nutritional support is an important aspect of the treatment of patients with IBD, not because specific types of diets are useful in alleviating the inflammatory conditions but because patients with moderate to severe disease are often malnourished, either because the inflammatory process results in significant malabsorption or maldigestion or because of the catabolic effects of the disease process. Elevated levels of interleukin-6 and TNF-α are known to increase protein turnover, resulting in protein loss and muscle wasting.[37] Malabsorption may occur in the patient with CD with inflammatory involvement of the small bowel, where many nutrients are absorbed, as well as in patients who have undergone multiple small bowel resections with subsequent reduction in absorptive surface ("short gut"). Maldigestion with accompanying diarrhea can occur if there is a bile salt deficiency in the gut.

Many specific diets have been tried to improve the condition of patients with IBD, but none has gained widespread acceptance. With each individual it may be helpful to eliminate specific foods that exacerbate symptoms. This elimination process must be conducted cautiously, as patients have been known to exclude a wide range of nutritious products without adequate justification. Some patients with IBD, although not the majority, have lactase deficiency; therefore, diarrhea may be associated with milk intake. For these patients, avoidance of milk or supplementation with lactase generally improves the patient's symptoms. Patients with small bowel strictures due to CD should avoid excessive high-residue foods, such as citrus fruits and nuts.[1]

The nutritional needs of the majority of patients can be adequately addressed with enteral supplementation.[36] In severe acute UC, enteral nutrition resulted in a significantly greater increase in serum albumin, fewer adverse effects related to the nutritional regimen, and fewer postoperative infections, as compared with isocaloric, isonitrogenous parenteral nutrition.[41] The regimens were similar with regard to remission rate and the need for colectomy. Consideration should be given to lipid administration for its caloric value, as well as in recognition of depleted peripheral fat stores in many IBD patients and the greater potential for fatty acid deficiency. The use of enteral nutrition for patients with CD is preferable, as favorable effects on modulation of proinflammatory cytokine production may lead to enhanced maintenance of nutritional stores and increased growth rates in children.[36,42,43] Likewise, use of enteral nutrition may facilitate induction of remission in up to 60% of patients with active CD and possibly reduce the use of corticosteroids.[36,42,44]

Parenteral nutrition may be used in the treatment of severe CD or UC. The use of parenteral nutrition allows complete bowel rest for patients with severe UC, which may alter the need for proctocolectomy. Parenteral nutrition has also been valuable in CD since remission may be achieved with parenteral nutrition in about 50% of patients.[45] In some patients, the disease may worsen when parenteral nutrition is stopped. Patients who have severe CD may require a course of parenteral nutrition to attain a reasonable nutritional status or in preparation for surgery, as poor perioperative nutritional status is associated with an increased incidence of postoperative complications.[37] Patients with enterocutaneous fistulas of various etiologies benefit from parenteral nutrition.[45] Parenteral nutrition may also be valuable in children or adolescents with growth retardation associated with CD, but surgery is often

necessary with severe disease. Home parenteral nutrition may be required for patients requiring long-term therapy, particularly those with "short gut" as a consequence of surgical resection. Lastly, parenteral nutrition is more costly and is associated with more complications, such as serious infections, compared with enteral nutrition. Therefore, use should be limited to those patients for whom enteral nutrition is not preferred or feasible.

There is a growing interest in using probiotic approaches for IBD. Probiotics may lead to reestablishment of normal bacterial flora within the gut by oral administration of live bacteria such as nonpathogenic *Escherichia coli*, bifidobacteria, lactobacilli, or *Streptococcus thermophilus*. Probiotic formulations have been effective in maintaining remission in some trials for patients with UC; however differences in methodology, probiotics used, and underlying treatments for IBD make comparison of trials difficult.[46–48] A formulation of *Bifidiobacterium*, *Lactobacilli*, and *Streptococci* (VSL #3) is marketed specifically for use in UC as an adjunctive therapy and for patients who have a surgically constructed ileal pouch to prevent pouchitits.[47] Review of evidence for the probiotic use in the induction and maintenance of CD has led to recommendations not supporting widespread use, but rather further investigation.[48–52]

Surgery

Even with medical therapy 30% to 40% of patients with UC and 70% to 80% of patients with CD require surgical intervention at some point in their life.[53] Although surgery (proctocolectomy) is curative for UC, this is not the case for CD. Surgical procedures involve resection of segments of intestine that are affected, as well as correction of complications (e.g., fistulas) or drainage of abscesses.

For UC, colectomy may be necessary when the patient has disease uncontrolled by maximum medical therapy or when there are complications of the disease such as colonic perforation, toxic dilatation (megacolon), uncontrolled colonic hemorrhage, or colonic strictures. Colectomy may be indicated for patients with long-standing disease (greater than 8 to 10 years), as a prophylactic measure against the development of cancer, and for patients with premalignant changes (severe dysplasia) on surveillance mucosal biopsies. The most common surgical procedures include proctocolectomy (after which the patient is left with a permanent ileostomy) and abdominal colectomy, with removal of the mucosa of the rectum and anastomosis of an ileal pouch to the anus (ileal pouch-anal anastamosis).[53] The risk from surgery for these patients is relatively low if the operations are performed on a nonemergent basis.

The indications for surgery with CD are not as well established as for UC, and surgery is usually reserved for the complications of the disease. A recognized problem with intestinal resection for CD is the high rate of recurrence. Surgery may be appropriate in well-selected patients who have severe or incapacitating disease or obstruction in spite of aggressive medical management. The surgical procedures performed include resections of the major intestinal areas of involvement. For some patients with severe rectal or perianal disease, particularly abscesses, diversion of the fecal stream is performed with a colostomy. Other indications for surgery include strictures, colon cancer, an inflammatory mass, or intestinal perforations or fistulas.

PHARMACOLOGIC THERAPY

Drug therapy plays an integral part in the overall treatment of IBD. None of the drugs used for IBD are curative; at best, they serve to control the disease process. Therefore, a reasonable goal of drug therapy is resolution of disease symptoms such that the patient can carry on normal daily functions. The major types of drug therapy used in IBD include aminosalicylates, corticosteroids, immunosuppressive agents (azathioprine, mercaptopurine, cyclosporine, and methotrexate), antimicrobials (metronidazole and ciprofloxacin), and agents to inhibit TNF-α (anti-TNF-α antibodies) or leukocyte adhesion and migration (natalizumab).

Sulfasalazine, an agent that combines a sulfonamide (sulfapyridine) antibiotic and mesalamine (5-aminosalicylic acid) in the same molecule, has been used for many years to treat IBD but was originally intended to treat arthritis. Sulfasalazine is cleaved by gut bacteria in the colon to sulfapyridine (which is mostly absorbed and excreted in the urine) and mesalamine (which mostly remains in the colon and is excreted in stool).[44,54–56]

The active component of sulfasalazine is mesalamine, and the mechanism of action is not well understood.[44,54–56] Cyclooxygenase or lipoxygenase inhibition alone does not entirely account for the agent's effects. Aminosalicylates may block production of prostaglandins and leukotrienes, inhibit bacterial peptide-induced neutrophil chemotaxis and adenosine-induced secretion, scavenge reactive oxygen metabolites, and inhibit activation of the nuclear regulatory factor NF-κB.[10] Sulfasalazine is often used initially before oral mesalamine derivatives when expense is an issue; however, it is not tolerated as well as the mesalamine alternatives.

Because the mechanism of action of sulfasalazine is not related to the sulfapyridine component and since sulfapyridine is believed to be responsible for many of the adverse reactions to sulfasalazine, mesalamine alone can be used. Mesalamine can be used topically as an enema or suppository for the treatment of proctitis or given orally in slow-release formulations that deliver mesalamine to the small intestine and colon (Table 41–5 and Fig. 41–1). Slow-release

TABLE 41-5 Mesalamine Derivatives for Treatment of Inflammatory Bowel Disease

Product	Trade Name(s)	Formulation	Dose per Day	Site of Action
Sulfasalazine	Azulfidine Azulfidine Entabs Sulfazine Sulfazine EC	Immediate release or enteric coated tablets	4–6 g	Colon
Mesalamine	Rowasa	Enema	1–4 g	Rectum, distal colon
	Asacol Asacol HD	Mesalamine tablet coated with Eudragit-S (delayed-release acrylic resin)	2.4–4.8 g	Distal ileum and colon
	Pentasa	Mesalamine capsules encapsulated in ethylcellulose microgranules	2–4 g	Small bowel and colon
	Lialda	Mesalamine tablet formulated with MMX delayed-release technology (pH-dependent outer coat with polymeric matrix core); allows for once daily dosing	1.2–4.8 g	Colon
	Apriso	Mesalamine capsule formulated with enteric-coated granules in a delayed-release polymer matrix; allows for once daily dosing	1.5 g	Colon
	Canasa	Mesalamine suppository	500–1000 mg	Rectum
Olsalazine	Dipentum	Dimer of 5-aminosalicylic acid oral capsule	1.5–3 g	Colon
Balsalazide	Colazal	Capsule	6.75 g	Colon

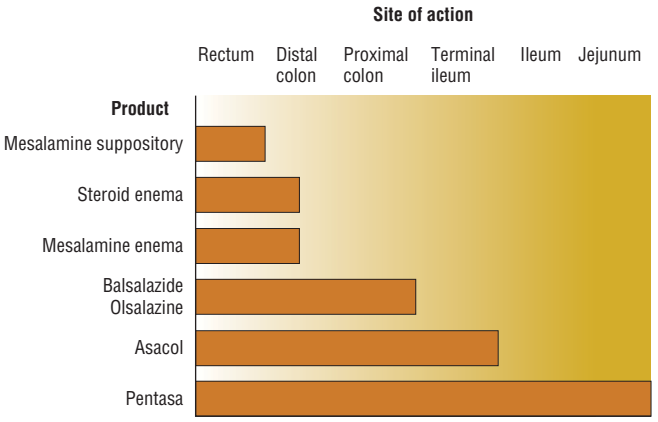

FIGURE 41-1. Site of activity of various agents used to treat inflammatory bowel disease.

oral formulations of mesalamine, such as Pentasa, release mesalamine from the duodenum to the ileum, with up to 59% of the drug passing into the colon.[54] A tablet formulation of mesalamine (Lialda), uses a pH-dependent coating in combination with a polymeric matrix core, and releases drug evenly throughout the colon, also allowing for once daily dosing.[55,56] A once daily capsule formulation of mesalmine (Apriso) utilizes enteric-coated mesalamine granules in a polymer matrix for delayed and extended delivery of mesalamine to the colon.[56] The use of the once daily oral mesalamine preparations may help to enhance adherence thus improving long-term outcomes. Olsalazine is a dimer of two 5-aminosalicylate molecules linked by an azo bond. Mesalamine is released in the colon after colonic bacteria cleave olsalazine. Balsalazide is a mesalamine prodrug that couples mesalamine with the inert carrier molecule 4-aminobenzoyl-B-alanine and is enzymatically cleaved in the colon to release mesalamine. The recommended daily doses of the oral mesalamine derivatives are intended to approximate the molar equivalent of mesalamine present in 4 g of sulfasalazine. Because the oral mesalamine formulations are coated tablets or granules, they should not be crushed or chewed. Unlike sulfasalazine, all of these agents are safe to use for patients with sulfonamide allergies.

Corticosteroids and adrenocorticotropic hormone have been widely used for the treatment of UC and CD, given parenterally, orally, or rectally.[57] Corticosteroids modulate the immune system and inhibit production of cytokines and mediators. It is not clear whether the most important steroid effects are systemic or local (mucosal). Budesonide is a corticosteroid that is administered orally in a controlled-release formulation designed to release in the terminal ileum. The drug undergoes extensive first-pass metabolism; so systemic exposure is thought to be minimized.[58] Immunosuppressive agents such as azathioprine, mercaptopurine, methotrexate, or cyclosporine are also used for the treatment of IBD (Table 41–6).

Azathioprine and mercaptopurine are effective for long-term treatment of both CD and UC.[39,40,44,59] These agents are generally reserved for patients who are refractory to or dependent upon corticosteroids. They are usually used in conjunction with mesalamine derivatives and/or steroids and must be used for extended periods of time, ranging from a few weeks up to 12 months, before benefits may be observed.[59] Early use of azathioprine in combination with infliximab for patients with CD who are naive to treatment with immunosuppressive agents or corticosteroids improves outcomes versus use of these agents individually.[60]

Azathioprine and mercaptopurine may be associated with serious adverse effects such as lymphomas, pancreatitis, or nephrotoxicity.[59] Predisposition to development of these adverse effects may be related to polymorphisms in the enzyme thiopurine methyl transferase (TPMT), which is partially responsible for activation and metabolism of these drugs.[61] The Food and Drug Administration recommends that patients be tested for TPMT genotype and phenotype or activity prior to initiating therapy to identify patients that may have reduced TPMT activity and thus be at risk for toxicity. Adjusting azathioprine and mercaptopurine doses by measuring concentrations of metabolites, particularly 6-thioguanine (6-TGN), may be useful, with higher levels associated with greater remission rates.[61]

Cyclosporine has also been of short-term benefit in treatment of acute, severe UC when used in a continuous intravenous infusion. Lower dose continuous infusions (2 mg/kg vs 4 mg/kg daily), or oral daily doses of 5 to 6 mg/kg in conjunction with steroids may be an effective option for those with fulminant disease.[62] The agent poses a risk of nephrotoxicity and neurotoxicity. Some studies evaluating tacrolimus for the treatment of IBD suggest a potential role for use for patients with fistulizing CD, for patients unresponsive to steroids or infliximab, or in management of some extraintestinal manifestations.[63] Methotrexate 25 mg given intramuscularly or subcutaneously once weekly is useful for treatment and maintenance of CD and may result in steroid sparing effects, while data supporting use in UC are lacking.[40,64,65]

Antimicrobial agents, particularly metronidazole, are frequently used in attempts to control CD but are not typically useful in UC.[40,52,66] Metronidazole is of value for some patients with active CD, particularly involving the perineal area or when fistulas or abscesses are present.[52,66] Likewise, there may be a role for use of metronidazole in combination with azathioprine to reduce postsurgical recurrence of CD.[52] The mechanism of metronidazole's

TABLE 41-6 Immunomodulator, Immunosuppressive, and Biologic Agents for the Treatment of Inflammatory Bowel Disease

Product	Trade Name(s)	Indication(s)[a]	Dose
Azathioprine	Imuran, Azasan	CD, UC	1.5–2.5 mg/kg per day orally
Mercaptopurine	Purinethol	CD, UC	1.5–2.5 mg/kg per day orally
Methotrexate	Rheumatrex, Trexall	CD	15–25 mg weekly (IM[a]/SC[a]/orally)
Cyclosporine	Sandimmune	CD, UC	4 mg/kg per day IV[a] continuous infusion
Infliximab	Remicade	CD, UC	Induction: 5 mg/kg IV at 0, 2, and 6 weeks; 10 mg/kg per dose IV for non-responders Maintenance: 5 mg/kg IV every 8 weeks
Adalimumab	Humira	CD	Induction: 160 mg SC day 1 (given as four 40 mg injections in 1 day or as two 40 mg injections per day for 2 consecutive days), then 80 mg SC 2 weeks later (day 15) Maintenance: 40 mg SC every other week, starting on day 29 of therapy
Certolizumab	Cimzia	CD	Induction: 400mg SC initially, then 400 mg SC at 2 and 4 weeks Maintenance: 400 mg SC every 4 weeks if initial response
Natalizumab	Tysabri	CD	Induction/maintenance: 300 mg IV every 4 weeks

[a]CD = Crohn's disease, UC = ulcerative colitis, IV = intravenous, SC = subcutaneous, IM = intramuscular

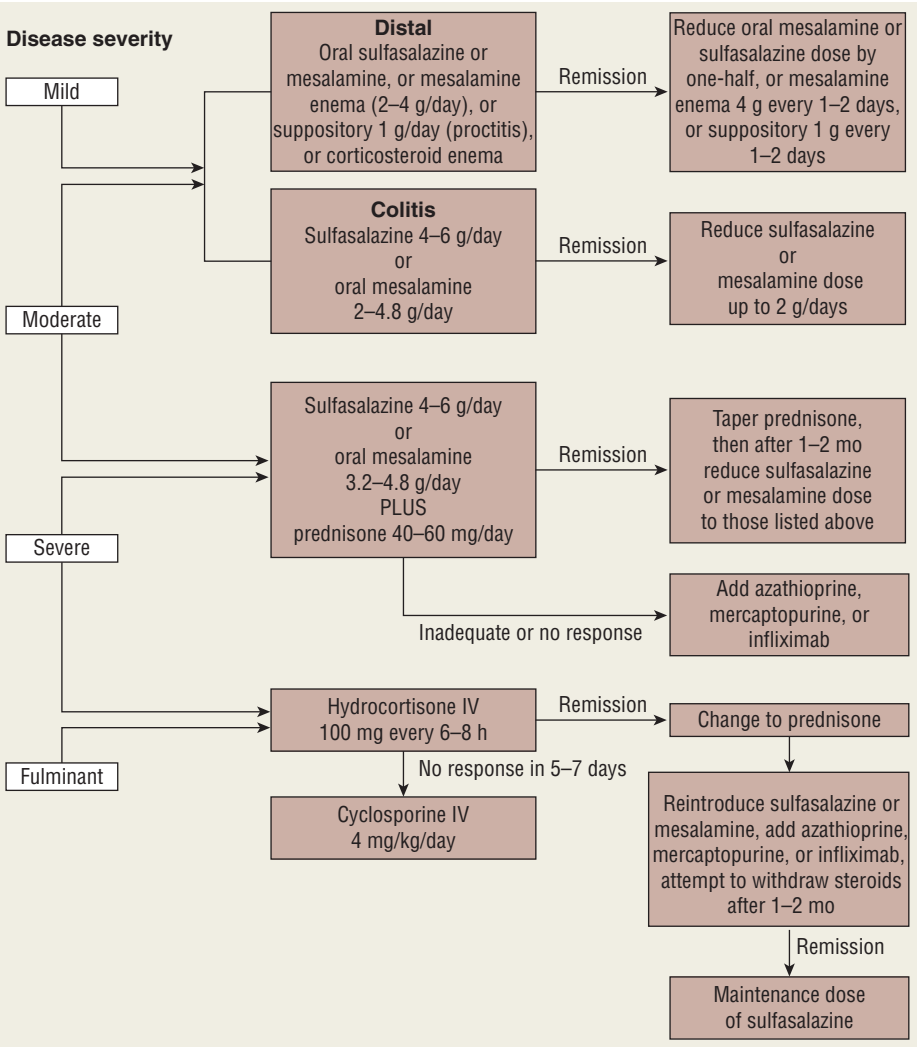

FIGURE 41-2. Treatment approaches for ulcerative colitis.

effect on CD has not been determined but is theorized to relate to interruption of a bacterial role in the inflammatory process. Ciprofloxacin has also been used for treatment of IBD, with some studies demonstrating efficacy for CD when used in combination with metronidazole.[40] Rifaximin, a nonabsorbable antibiotic, has also shown some efficacy in treatment of both UC and CD.[40,52,66]

Three biologic agents are now available for treatment of IBD that target TNF-α.[67] Infliximab is an IgG_1 chimeric monoclonal antibody that is administered intravenously and binds TNF-α and inhibits its inflammatory effect in the gut. The agent is useful for moderate to severe active CD and UC disease, as well steroid-dependent or fistulizing disease, as both an induction and maintenance therapy. Adalimumab is also an IgG1 antibody to TNF-α; however, this agent, unlike infliximab, is fully humanized and contains no murine sequences. Theoretically, the lack of a murine component in adalimumab reduces antibody development seen with use of infliximab. This agent can be administered subcutaneously. Adalimumab is a treatment option for patients with moderate to severe active CD previously treated with infliximab who have lost response. Certolizumab pegol is a humanized pegylated Fab fragment directed against TNF-α that is administered subcutaneously and demonstrates similar efficacy to adalimumab and infliximab.[67]

Lastly, natalizumab is a novel biologic agent that inhibits leukocyte adhesion and migration by targeting α_4 integrin.[18,67] This agent can be used in the treatment of CD for patients who are unresponsive to other therapies, including corticosteroids and TNF-α inhibitors.

Ulcerative Colitis

Mild to Moderate Disease Most patients with active UC that have mild to moderate disease can be managed on an outpatient basis with oral or topical (rectal) therapies (Fig. 41–2, Table 41–7). The first line of drug therapy for patients with extensive disease is oral sulfasalazine or an oral mesalamine derivative.[39] Topical mesalamine in an enema or suppository formulation is more effective than oral mesalamine or topical steroids for distal disease.[29,39] The combination of oral and topical mesalamine is more effective than either alone for active distal disease.[29,39,68,69] When given orally, usually 4 to 6 g/day, and possibly up to 8 g/day, of sulfasalazine is required to attain control of active inflammation. There does not appear to be an increased rate of response with increased dosage over 6 g/day, although side effects increase. Even with the use of adequate doses, patient improvement usually takes 4 weeks and sometimes longer.[39] The dosage of sulfasalazine that can be given is usually limited by the patient's tolerance of the agent; most adverse effects of sulfasalazine are dose related (GI disturbances, headache, and arthralgia).[38] Sulfasalazine therapy should be instituted at 500 mg/day and increased every few days up to 4 g/day or the maximum tolerated. It should not be used for patients with allergy to sulfonamide-containing drugs.

TABLE 41-7 Levels of Evidence for Therapeutic Interventions in Inflammatory Bowel Disease

Interventions	Evidence Grades[a]
Ulcerative colitis	
Mild to moderate active distal disease may be treated with oral aminosalicylates, topical mesalamine, or topical steroids.	A
Combined oral and topical aminosalicylates are more effective than either is alone for mild to moderate active distal disease.	A
Oral prednisone in doses of 40–60 mg/day or 1 mg/kg/day may be used in patients with mild to moderate distal disease unresponsive to oral or topical aminosalicylates.	B
Sulfasalazine in doses of 4–6 g/day or an alternate aminosalicylate in doses of up to 4.8 g/g of the active 5-aminosalicylate moiety are effective for induction of mild to moderate extensive colitis.	A
Infliximab is effective for moderate to severe disease in those patients not responding to corticosteroids or an immunosuppressive agent.	A
Systemic corticosteroids are effective in moderate to severe active disease.	A
Hospitalization for parenteral steroids is indicated for patients with severe disease or those failing to respond to oral steroids.	A
Failure to demonstrate improvement following 7–10 days of parenteral steroids in patients with severe disease is an indication for cyclosporine or colectomy; mesalamine suppositories (proctitis) and enemas (distal colitis) are effective in maintenance of remission with doses as infrequently as every third night.	B
Sulfasalazine, mesalamine, or balsalazide are effective in maintenance of remission of distal disease; combining oral and topical mesalamine is more effective than is either alone.	A
Sulfasalazine, olsalazine, mesalamine, and balsalazide are effective in preventing relapses in patients with mild to moderate extensive disease.	A
Corticosteroids are not effective as maintenance treatment.	A
Azathioprine, mercaptopurine, or infliximab are effective in lowering or eliminating corticosteroid use in corticosteroid-dependent patients.	A
Azathioprine, mercaptopurine, or infliximab may be effective in patients with severe disease flares or those requiring retreatment with corticosteroids within 1 year.	C
Oral cyclosporine is effective for patients with corticosteroid refractory disease but requires concomitant administration of azathioprine or mercaptopurine.	C
Infliximab therapy is effective for maintenance if there is an initial response.	A
Crohn's disease	
Oral aminosalicylates are effective for mild to moderate ileal, ilealocolonic, or colonic active disease.	D
Metronidazole may be effective in patients not responding to sulfasalazine.	D
Ileal release budesonide is effective for mild to moderate ileal or right-sided colonic disease.	A
Topical hydrocortisone is effective for distal colonic inflammation.	A
Systemic corticosteroids are effective in moderate to severe active disease.	A
Systemic corticosteroids are not effective for patients with perianal fistulas.	C
Hospitalization for parenteral steroids is indicated for patients with severe disease or those failing to respond to oral steroids.	A
Parenteral methotrexate is effective for induction of remission in patients with active disease and for reducing corticosteroid dependency.	B
Infliximab, adalimumab, and certolizumab are effective for moderate to severe disease in those patients not responding to corticosteroids or an immunosuppressive agent.	A
Infliximab and adalimumab are effective for those patients with fistulas who have not responded to antibiotics, immunosuppressive agents, or surgical drainage.	A
High-dose oral cyclosporine (7.6 mg/kg) has short-term efficacy in patients with active disease.	B
Intravenous cyclosporine is effective for the treatment of fistulizing disease.	B
Corticosteroids are not effective as maintenance treatment.	A
Budesonide is effective as short-term maintenance therapy (3 months) but not long term.	A
Azathioprine, mercaptopurine, or infliximab are effective in lowering or eliminating corticosteroid use in corticosteroid-dependent patients.	A
Azathioprine, mercaptopurine, or infliximab may be effective in patients with severe disease flares or those requiring retreatment with corticosteroids within 1 year.	A
Azathioprine or mercaptopurine is effective for maintenance of remission regardless of disease distribution.	A
Azathioprine or mercaptopurine may be effective for treating perianal or enteric fistulae.	C
Methotrexate maintenance therapy (15–25 mg IM weekly) is effective for patients whose active disease has responded to IM methotrexate.	A
Methotrexate 25 mg IM for up to 16 weeks followed by 15 mg IM weekly is effective for patients with chronic active disease.	A
Infliximab, adalimumab, and certolizumab therapy is effective for maintenance if there is an initial response.	A

[a]A, Homogenous evidence from multiple well-designed, randomized (therapeutic) or cohort (descriptive) controlled trials, each involving a number of participants to be of sufficient statistical power; B, evidence from at least 1 large well-designed clinical trial with or without randomization from cohort or case control analytic studies or well-designed metaanalysis; C, evidence based on clinical experience, descriptive studies, or reports of expert committees; D, not rated.

From references 29, 36, 40, and 76.

Oral mesalamine derivatives (such as those listed in Table 41–5) are reasonable alternatives to sulfasalazine for treatment of mild to moderate UC. Oral mesalamine products are used for patients with extensive disease, while topical agents, such as enemas and suppositories, are used for distal disease. Mesalamine is more effective than placebo but no more effective than sulfasalazine for extensive disease.[70,71] Mesalamine preparations are typically better tolerated, and the majority of patients intolerant to sulfasalazine or topical steroids should tolerate one of the other oral mesalamine derivatives.[38,39] Dose-related effects do exist, and when used orally for active extensive disease, the equivalent of 4.8 g of the active 5-aminosalicylic acid moiety should be administered when possible.[39,70,71] Studies comparing daily doses of 2.4 g versus 4.8 g of mesalamine (Asacol formulation) for patients with moderate active UC demonstrated greater efficacy at 6 weeks of therapy (58% vs 72%, $P < 0.05$).[68,72,73] While the dosage range for Pentasa is 2 to 4 g/day, 4 g/day appears to be more effective.[70] Olsalazine is effective for treatment of mild to moderate UC, however, 15% to 25% of patients taking olsalazine experience severe diarrhea, often necessitating discontinuation of the drug. This results from a direct osmotic effect of the drug to induce small bowel fluid secretion. For this reason it is not the drug of first choice.[39] Balsalazide is effective for treatment of mild to moderate UC.[74,75] The new once daily formulations of mesalamine offer similar efficacy in mild to moderate UC with the benefit of once daily dosing and potentially lower pill burden.[55,56] When used topically, mesalamine suppositories will only reach to approximately 10 to 20 cm with the lower GI tract and therefore should be reserved for patients with proctitis. Enema formulations will reach to the splenic flexure and therefore can be used for distal disease.[29,39]

Moderate to Severe Disease 7 Systemic corticosteroids have a place in the treatment of moderate to severe active UC regardless of disease location or of those patients who are unresponsive to maximal doses of oral and/or topical mesalamine derivatives.[39,76] Oral steroids (usually up to 1 mg/kg per day of prednisone equivalent or 40 to 60 mg daily) may be used for patients who do not have an adequate response to sulfasalazine or mesalamine.[39] The response to steroids may be evident sooner than sulfasalazine or the aminosalicylates. Oral steroids should not be used as initial therapy for mild to moderate UC, mainly because of the known risks of steroid use. If steroids are used to attain remission, tapered drug withdrawal should be accomplished to minimize long-term steroid exposure.

Topically administered steroids given as suppositories, enemas, or foams can be used as initial therapy for patients with ulcerative proctitis or distal colitis. Topical agents are also beneficial for treatment of tenesmus. With these agents, local actions are believed to be responsible for drug effects. Topical steroids are effective in the treatment of active, distal UC. However, rectal mesalamine is more effective than rectal steroids for inducing remission.[29,39,68,69,76]

Infliximab is another viable option for patients with moderate to severe active UC who are unresponsive to steroids or other immunosuppressive agents.[67,68,76,77] For outpatients with moderately active UC, infliximab demonstrated response rates of up to 69% at 8 weeks following initial doses of 5 mg/kg.[78] Studies in hospitalized patients have shown mixed results, with some demonstrating reduced rates of colectomy for patients receiving infliximab.[67,77,79,80]

Nicotine has been proposed as a treatment for UC (but not as a treatment for CD) based on the observation of the onset of a flare of UC after smoking cessation in some individuals. While less effective than aminosalicylates, transdermal nicotine in daily doses of 15 to 25 mg may improve symptoms for patients with mild to moderate active UC, particularly for patients who are ex-smokers, and can be considered as an adjunctive therapy in both distal and extensive disease.[24,29,39,81]

Severe or Fulminant Disease Patients with uncontrolled severe colitis or who have incapacitating symptoms require hospitalization for effective management. Under these conditions, patients generally receive nothing by mouth to put the bowel at rest. Most medication is given by the parenteral route. Sulfasalazine or mesalamine derivatives are not beneficial for treatment of severe colitis because of rapid elimination of these agents from the colon with diarrhea, thereby not allowing sufficient time for gut bacteria to cleave the molecules. It is difficult to evaluate drugs in this setting, because patients with severe disease almost always receive additional medications including steroids.

Steroids have been valuable in the treatment of severe disease because the use of these agents may allow some patients to avoid colectomy. Intravenous hydrocortisone 300 to 400 mg daily in three divided doses or methylprednisolone 48 to 60 mg once daily are considered first-line agents.[39,76] Methylprednisolone is typically preferred due to its lesser mineralocorticoid effects. A trial of steroids is warranted in most patients before proceeding to colectomy, unless the condition is grave or rapidly deteriorating. The length of the medical trial before consideration of surgery is open to debate. Steroids increase surgical risk, particularly infectious risk, if an operation is required later. After a colectomy is performed, steroids should no longer be required for the disease; however, they must be withdrawn gradually (usually over 3 to 4 weeks) to avoid hypoadrenal crisis due to adrenal suppression.

8 Patients who are unresponsive to parenteral corticosteroids after 7 to 10 days should receive cyclosporine by intravenous infusion. Seventy percent to 80% of hospitalized patients who are unresponsive to corticosteroids will respond to cyclosporine.[62] Continuous intravenous infusion of cyclosporine (4 mg/kg per day) is typically effective in steroid-resistant acute severe UC and may reduce the need for emergent colectomy.[62,82] Intravenous cyclosporine has also been recommended as an alternative to steroids for patients with severe attacks of UC (fulminant colitis).[83] Patients who are controlled on intravenous cyclosporine can then be switched to an oral cyclosporine taper regimen with subsequent transition to azathioprine or mercaptopurine.[76] As mentioned earlier, infliximab is also an alternative to cyclosporine and may also deter the need for colectomy for patients with severe disease not responsive to steroids.[67,76–79]

Maintenance of Remission

9 After remission from active disease is achieved, the goal of therapy is to then maintain remission. The major agents used for maintenance of remission are sulfasalazine and the mesalamine derivatives.[70,84] The value of sulfasalazine in preventing recurrences has been documented in several placebo-controlled trials.[84] Sulfasalazine, most commonly dosed at 2 g/day, was superior to mesalamine when using the main end point of failure to maintain endoscopic or clinical remission [OR 1.29 (95% CI, 1.05-1.57)].[84] Sulfasalazine also appears to be more effective in maintaining remission compared with the newer agents, such as olsalazine.

For patients with distal disease or proctitis, mesalamine enemas or suppositories are considered first-line agents.[29,39,69] The frequency of administration of topical agents may possibly be lessened to every third night over time. Oral agents, including sulfasalazine, mesalamine, and balsalazide, are also effective options if patients do not wish to use topical preparations.[29,39,69] The combination of topical and oral mesalamine is superior to either regimen alone for maintenance therapy.

CLINICAL CONTROVERSY

A major question about the use of aminosalicylates for maintenance of remission of UC is whether they reduce the patient's risk of developing colorectal cancer. It has been suggested that mesalamine, in doses >1.2 g/day, is protective against the development of colorectal cancer; however, this is not entirely supported by controlled trials. Given the often slow development of colorectal cancer and the relapsing nature of UC, these significantly limit the ability to conduct long-term surveillance studies for patients in remission.

Steroids do not have a role in the maintenance of remission with UC because they are ineffective.[39] Steroids should be gradually withdrawn after remission is induced (over 3 to 4 weeks). If they are continued, the patient will be at risk for steroid-induced adverse effects without likelihood of benefits. For patients who require chronic steroid use (steroid dependency), there is a strong justification for alternative therapies or colectomy. Azathioprine is effective in preventing relapse of UC for periods exceeding 4 years.[59,72,76,85] However, 3 to 6 months may be required before beneficial effects are noted. For patients who initially respond to infliximab, continued dosing of 5 mg/kg as maintenance therapy every 8 weeks is another alternative for corticosteroid-dependent patients or those failing immunosuppressive therapy.[67,76,77]

CROHN'S DISEASE

Management of CD often proves more difficult than management of UC, partly because of the greater complexity of presentation with

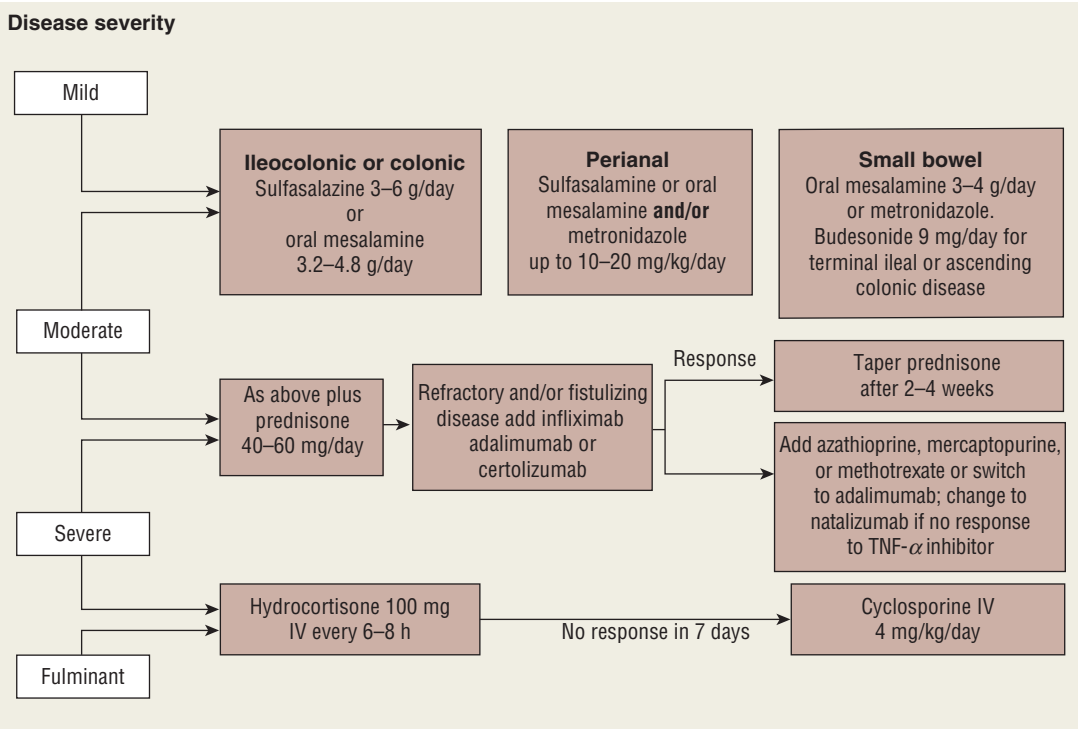

FIGURE 41-3. Treatment approaches for Crohn's disease.

CD[86] (Fig. 41–3, Table 41–6). The disease may involve any segment of the GI tract, from mouth to anus, and may involve other visceral structures and soft tissues through fistulization. There is a greater reliance on drug therapy with CD because resection of all involved intestine may not be possible. Unfortunately, recurrence of CD is common following surgery with reported rates of up to 64% recurrence following surgical resection of affected areas of bowel.[53]

Mild to Moderate Active Crohn's Disease

The goal of treatment for active CD is to achieve remission; however, in many patients, reduction of symptoms so the patient may carry out normal activities or reduction of the steroid dose required for control is a significant accomplishment. In the majority of patients, mild to moderate active CD is treated with sulfasalazine or mesalamine derivatives, while steroids, azathioprine, mercaptopurine, methotrexate, biologic agents, or metronidazole are frequently for moderate to severe disease.

Sulfasalazine, when administered in daily doses of 3 to 6 g, is slightly superior to placebo for patients with mild to moderate CD and is more effective when CD involves the colon.[40,87] Mesalamine formulations such as Pentasa or Asacol have the ability to release mesalamine in the small bowel thus targeting ileal disease, yet have demonstrated variable results for patients with active CD.[86,87] Only a few small trials utilizing Asacol at 3.8 g/day or Pentasa at 4g/day have demonstrated superiority to placebo for treatment of active CD.[86,87] Despite variable effectiveness, the mesalamine derivatives may be better tolerated than sulfasalazine, particularly at higher doses. Thus, a trial of sulfasalazine or an oral mesalamine derivative is reasonable as initial therapy for patients with mild to moderate active CD with ileal, ileocolonic, or colonic involvement.[39]

Systemic corticosteroids are frequently used for the treatment of active CD, particularly with more moderate to severe presentations; however, controlled release budesonide (Entocort) is a viable first-line option for patients with mild to moderate ileal or right-sided (ascending colonic) disease.[40,58,76,87,88] This agent is superior to placebo and has demonstrated superiority to mesalamine and reported rates of remission rates of up 69% at 8 weeks in some trials.[40,87,88] For this reason, recent guidelines advocate use of budesonide 9 mg/day as a first-line option for patients with CD confined to the ileum and/or right colon.[40]

Metronidazole (given orally up to 20 mg/kg per day in divided doses) has demonstrated variable efficacy but may possibly be useful in some patients with CD, particularly for patients with colonic or ileocolonic involvement or for those patients with perineal disease.[66,86,87,89] For most patients with colonic or perineal disease, metronidazole would be added to a mesalamine product or steroids as adjunctive therapy, where satisfactory control of CD is not gained with first-line agents, or in attempts to reduce steroid dosage.[52,66] Ciprofloxacin 1 g/day has gained attention as an alternative to metronidazole and has demonstrated some efficacy in small trials only.[52,66,77,86,87] The combination of ciprofloxacin with metronidazole appears to be efficacious in some patients with perianal disease.[66,87,89] Antibiotics demonstrate minimal efficacy in mild to moderate active CD and thus are not recommended for routine use.[40,87]

Moderate to Severe Active Crohn's Disease

Oral systemic steroids, such as prednisone 60 mg/day, are generally considered first-line therapies for moderate to severe active CD and are effective in inducing remission for up to 70% of patients. Oral systemic steroids should be reserved for patients with moderate to severe disease who have failed aminosalicylates or budesonide.[40,76,86] Hospitalized patients with severe or fulminant disease or those who are unable to tolerate oral therapy are candidates for administration of parenteral steroids.[40,76] Systemic steroids do not appear to be effective for treatment of perianal fistulas.[76,89]

⑩ The immunomodulators (azathioprine and mercaptopurine) are effective in maintaining steroid-induced remission and are generally limited to use for patients not achieving adequate response to standard medical therapy or to reduce steroid doses when high steroid doses are required.[59,76,86,90] Azathioprine and mercaptopurine have both demonstrated long-term benefits for patients with CD.[59,85] The usual doses of azathioprine is 2 to 3 mg/kg per day, and for mercaptopurine to 1.5 mg/kg per day.[76] Starting doses are typically 50 mg/day and increased at 2-week intervals; however,

complete blood counts with differential should be monitored every 2 weeks while doses are being titrated.[76] The onset of therapeutic effects are delayed with both azathioprine and mercaptopruine, and a minimum of 3 to 4 months is often required to see clinical benefits.[76,86]

As mentioned previously, clinical response to mercaptopurine may be related to whole-blood concentrations of the metabolite 6-TGN, while toxicity is correlated with concentrations of another metabolite, 6-methylmercaptopurine.[14,59,61,91] Determination of TPMT activity is recommended to determine which patients require lower doses of these agents.[15,59,76] Alternatively, a newer strategy for evaluating a patient's risk for toxicity is to perform a TPMT genotype or phenotype.[59,76,91] This is recommended prior to therapy with subsequent dose adjustments based on the patient's genotypic profile.[76]

CLINICAL CONTROVERSY

While thiopurines, such as azathioprine and mercaptopurine, are effective for maintenance of remission of CD, it is debated how long treatment should be continued once remission is achieved. Evidence has demonstrated efficacy of these agents in maintaining remission for greater than 4 years; however, some authors argue that long-term exposure to these potentially toxic agents outweighs the benefit.

11 Although mostly used in the setting of maintenance therapy, methotrexate is another option for use as induction therapy for patients with moderate to severe CD.[86] Use of a weekly intramuscular or subcutaneous injection of 25 mg has demonstrated efficacy for induction of remission in CD and has also demonstrated corticosteroid-sparing effects.[40,76,86,92] While there are risks of bone marrow suppression, hepatotoxicity, and pulmonary toxicity, use of low-dose methotrexate appears relatively safe when continued as maintenance therapy if proper monitoring is implemented.

Infliximab is a well-established treatment option for moderate to severe active CD for patients failing immunosuppressive therapy, in those who are corticosteroid dependent, and for treatment of fistulizing disease.[60,67,76,93] In large trials, a 5 mg/kg single intravenous infusion of infliximab resulted in clinical improvement in 58% of patients at 2 weeks and 65% of patients at 8 weeks.[67,93] Continued dosing of 5 mg/kg at 2 and 6 weeks following the initial dose leads to higher response rates and is recommended as the regimen of choice for induction therapy in active disease.[76] Response rates of up to 62% in the reduction of number of draining fistulas have been reported following induction therapy and continued maintenance dosing with infliximab.[67,93,94] Patients who receive infliximab often develop antibodies to infliximab (ATI), which can result in increases in the occurrence of serious infusion reactions and loss of response to the drug. Up to 10% of patients per year require discontinuation of infliximab due to adverse effects and loss of efficacy related to development of ATIs.[67] Strategies to reduce ATI formation include administration of a second dose within 8 weeks of the first dose, concurrent administration of steroids (hydrocortisone 200 mg intravenously on the day of the infusion or oral prednisone the day prior), and use of concomitant immunosuppressive agents.[67,76,93] Induction of tolerance utilizing a dose escalation technique was also effective in administering infliximab to patients with previous severe infusion reactions.[95] As mentioned previously, use of infliximab in combination with azathioprine may lead to better outcomes in steroid or immunosuppressive naive patients.[60]

Adalimumab is another viable option for moderate to severe CD. Trials evaluating treatment with adalimumab for patients with moderately to severely active CD who have lost response to infliximab have demonstrated up to a 54% complete response in some instances.[67,96–98] Certolizumab has also demonstrated efficacy in moderate to severe CD with patients who have a baseline CRP of greater than 10 mg/dL exhibiting the best response rates, reported as 37% at 6 weeks versus 26% for placebo.[67,99] Natalizumab is reserved for patients who do not respond to steroids or the TNF-α inhibitors. Patients who initially responded to natalizumab treatment had rates of sustained response reported as 61% versus 28% for placebo at week 36.[100]

Cyclosporine is typically not recommended for treatment of CD except for acute management of patients with severe fistulizing disease.[76,94,101] Up to 83% of patients with refractory fistulas responded to intravenous cyclosporine (4 mg/kg per day) within a mean of 7.9 days.[86] The dose of cyclosporine is important in determining efficacy. An oral dose of 5 mg/kg per day is ineffective, whereas 7.6 mg/kg per day has demonstrated effectiveness in some trials.[76,101] However, toxic effects limit the routine use of this higher dosage. At present, the therapeutic blood or plasma concentration range for cyclosporine has not been established for CD, but whole-blood trough concentrations of 300 to 500 ng/mL for intravenous therapy or 200 to 400 ng/mL for oral therapy have been established.[76,86] When using cyclosporine clinicians should recognize the accompanying long-term risk of renal toxicity and infection, as well as the potential for drug interactions.

Maintenance of Remission

Prevention of recurrence of disease is typically more difficult with CD than with UC. There is minimal evidence to support that sulfasalazine and oral mesalamine derivatives are effective therapies for maintenance of CD following medically-induced remission.[86,87,102,103] Despite these findings, an attempt to maintain remission with sulfasalazine and oral mesalamine following a medically-induced remission is reasonable given the favorable side-effect profile and cost of these drugs compared with the immunosuppressive and biologic agents.[86] Mesalamine does appear to have some efficacy in preventing post surgical relapse following resection, with absolute risk reductions of 10% to 15% for relapse reported in some studies.[103,104]

Systemic steroids have no place in the prevention of recurrence of CD. These agents do not appear to alter the long-term course of the disease and predispose patients to serious adverse effects with long-term use.[40,76,105] Budesonide at maintenance doses of 6 mg/day has demonstrated efficacy in maintaining remission at 3 months; however, use longer than this is generally not recommended, as a loss of efficacy is seen after this time frame.[76,106] Despite this recommendation, use of budesonide as maintenance therapy for up to 1 year results in low rates of clinically important adverse effects.[107]

Azathioprine, mercaptopurine, and methotrexate are useful for some patients with CD to maintain remission. Azathioprine and mercaptopurine are effective in maintaining remission in CD for up to 4 years, particularly in steroid-induced remission, and therefore these drugs are generally considered first-line agents.[40] Patients who may benefit from these agents include those with quiescent disease who are steroid dependent or refractory, in postsurgical patients to prevent recurrence, those with frequent flares requiring steroids, and those patients with perianal or enteric fistulas.[59,76,86] For patients who initially respond to methotrexate, continued dosing at 15 mg intramuscularly once weekly is also effective in maintaining remission.[76,86] This agent has steroid sparing effects and thus represents an alternative therapy to azathioprine and mercaptopurine.

Infliximab infusion given at a dose of 5 mg/kg every 8 weeks is more effective than placebo in maintaining remission for patients who initially respond to infliximab for active CD.[67,68,76,78,93] An increase in the dose to 10 mg/kg is possible if loss of efficacy over

time is evident. Additionally, infliximab is the effective maintenance therapy for fistulizing disease; however, given the high cost of this agent, some have questioned whether this approach is the most cost effective.[94] Adalimumab is also a treatment option for maintenance therapy of CD. Following induction therapy, doses of 40 mg subcutaneously every other week have resulted in clinical remission rates of 36% to 46% after 56 weeks of therapy.[108,109] Certolizumab is also effective for maintenance of CD, with remission rates for patients who initially responded reported as 49% at 26 weeks versus 29% with placebo[67,110] For patients treated with natalizumab who initially respond, maintenance therapy led to response rates of 44% compared with 26% for placebo ($P = 0.001$).[100]

CLINICAL CONTROVERSY

Use of immunomodulator agents, such as azathioprine and mercaptopurine, is becoming more common earlier in the course of IBD and for patients who may not fully respond to aminosalicylates. For patients that are receiving aminosalicylates who are started on immunomodulator agents it is unclear as to whether the aminosalicylate should be continued once the immunomodulator becomes effective. Continued use of aminosalicylates may aid in prevention of colorectal cancer; however, the effects of continued use on disease control drug toxicity and adherence to therapy are not known.[111]

SELECTED COMPLICATIONS

TOXIC MEGACOLON

The treatment required for toxic megacolon includes general supportive measures to maintain vital functions, consideration for early surgical intervention, and use of drugs (steroids, cyclosporine, and antimicrobials).[31,39] Aggressive fluid and electrolyte management is required for dehydration. Fluids and electrolytes may be lost through vomiting, diarrhea, and nasogastric intubation, as well as through fluid accumulation in the bowel. If the patient has lost significant amounts of blood, transfusion may be necessary. Opiates and medications with anticholinergic properties should be discontinued because these agents enhance colonic dilatation, thereby increasing the risk of bowel perforation. Broad spectrum antimicrobials that include coverage for gram-negative bacilli and intestinal anaerobes should be used as preemptive therapy in the event that perforation occurs.[31] Fortunately, perforation occurs in only 2% to 3% of cases.[39] If the patient is not on steroids, then high doses intravenous therapy should be administered to reduce acute inflammation. Emergent surgical intervention, mainly an abdominal colectomy with formation of an ileostomy, is an important consideration for patients with toxic megacolon and prevents death in some patients.[31,39,53]

SYSTEMIC MANIFESTATIONS

The common systemic manifestations of IBD include arthritis, anemia, and skin manifestations such as erythema nodosum and pyoderma gangrenosum, uveitis, and liver disease. These problems may be related to the inflammatory process. For some of these manifestations specific therapies can be instituted, whereas for others the treatment that is used for the GI inflammatory process also addresses the systemic manifestations.

Anemia occurs when there is significant blood loss from the GI tract. If the patient can consume oral medication, ferrous sulfate should be administered. If the patient is unable to take oral medication and the patient's hematocrit is sufficiently low, blood transfusions or intravenous iron infusions may be required.[34,35] Anemia may also be related to malabsorption of vitamin B12 or folic acid, particularly for patients who have had ileal resection, so these may also be required. Patients with IBD are also at high risk for bone loss, osteoporosis, and fractures.[35,112] Screening for osteoporosis via DXA is recommended for patients using steroids for >3 months, in postmenopausal females, males over age 50, and those who have sustained a low-stress fracture.[35,112] If the patient is deemed high risk for osteoporosis, vitamin D and calcium should be instituted. If osteoporosis is present, then calcium, vitamin D, and a bisphosphonate are recommended.[35,112] Corticosteroid use should be limited, and weight-bearing exercise initiated.

There are no consistently recommended therapies for apthous ulcers, liver disease, episcleritis, or uveitis associated with IBD. These manifestations are worse during exacerbations of the intestinal disease, and measures improving intestinal disease will improve these systemic manifestations. Unfortunately, this association has not been demonstrated consistently. For arthritis associated with IBD, aspirin or another NSAID may be beneficial, as might be steroids. However NSAID use may exacerbate the underlying IBD. Liver transplantation is being used more frequently for definitive treatment of primary sclerosing cholangitis. Infliximab and the other TNF-α inhibitors may alleviate some arthritic and skin manifestations of IBD such as ankylosing spondylitis, erythema nodosum, and pyoderma gangrenosum.[35,113]

SPECIAL CONSIDERATIONS

PREGNANCY

Either the occurrence or consideration of pregnancy may cause significant concerns for the patient with IBD. Patients with IBD have similar infertility rates as the general female population, thus the rate of normal childbirth is similar to that for healthy populations.[114–116] Some studies have noted a greater risk of spontaneous abortions for patients with IBD. Furthermore, there is a greater incidence of low-birth-weight infants for mothers with chronic idiopathic UC.[114] Pregnancy has minimal effects on the course of IBD.[114–116] Likewise, IBD appears to have little effect on the course of pregnancy, particularly if the IBD is quiescent at the time of conception.[114–116] Patients who are pregnant experience IBD recurrence rates similar to those of nonpregnant females. In addition, there is no justification for therapeutic abortion with IBD because termination of the pregnancy has not been observed to improve the disease.

Steroids and sulfasalazine may be administered during pregnancy with the same guidelines that would be applied to the nonpregnant patient.[114–116] Steroids given systemically do not appear to be detrimental to the fetus. Sulfasalazine is generally well tolerated; however, it does interfere with folate absorption, so supplementation with folic acid 1 mg twice daily should be used during the pregnancy.[114] Interestingly, sulfasalazine causes decreased sperm counts and reduced fertility in males.[114] This effect is reversible on discontinuation of the drug, and it is not reported with mesalamine. Immunosuppressive drugs (azathioprine and mercaptopurine) may be associated with fetal deformities in humans and are classified as pregnancy category D; however, they have been used commonly in IBD without detriment for most patients.[114–116] Infliximab, adalimumab, and certolizumab are classified as pregnancy category B drugs and appear to be relatively safe for use in pregnant patients.[114–116] Natalizumab is a pregnancy category C drug, and thus

may be used if benefit is thought to outweigh risk. Metronidazole may be used for short courses for treatment of trichomoniasis, but prolonged use should be avoided due to potential mutagenic effects.[114] Methotrexate should not be used during pregnancy, as it is a known abortifacient (category X).[76,114–116]

Although prednisone and prednisolone can be detected in breast milk, breast-feeding is believed to be safe for the infant when low doses of prednisone are used.[115] Sulfasalazine does not pose a risk of kernicterus, as levels of sulfapyridine in breast milk are low or undetectable. Metronidazole should not be given to nursing mothers because it is excreted into breast milk.[115,116]

ADVERSE DRUG EFFECTS

Drug intolerance often limits the usefulness of agents used to treat IBD. Many patients receiving sulfasalazine, mesalamine, corticosteroids, metronidazole, azathioprine, mercaptopurine, methotrexate, or biologic agents may experience undesired effects. In some cases, these adverse effects can be significant and require discontinuation of the therapy. Knowledge of the common or important adverse reactions will assist in avoiding or minimizing their effects.

Sulfasalazine is often associated with adverse drug effects, and these effects may be classified as either dose related or idiosyncratic.[117,118] The sulfapyridine portion of the sulfasalazine molecule is believed to be responsible for much of the sulfasalazine toxicity.[117] Dose-related side effects usually include GI disturbances such as nausea, vomiting, diarrhea, or anorexia but may also include headache and arthralgia. These adverse reactions tend to occur more commonly on initiation of therapy and decrease in frequency as therapy is continued. Approaches to the management of these adverse effects include discontinuing the agent for a short period and then reinstituting therapy at a reduced dosage with subsequent slower dose escalation, administration with food, or substituting another enteric-coated 5-ASA product.[117,118] Folic acid absorption is impaired by sulfasalazine, which may lead to anemia. Patients receiving sulfasalazine should receive oral folic acid supplementation.

Adverse effects that are idiosyncratic are not dose related and most commonly include rash, fever, or hepatotoxicity, as well as relatively uncommon but serious reactions such as bone marrow suppression, thrombocytopenia, pancreatitis, pneumonitis, interstitial nephritis, and hepatitis. For most patients with idiosyncratic reactions, sulfasalazine must be discontinued. In some patients who have experienced allergic reactions to sulfasalazine, a desensitization procedure can be instituted. By gradually increasing sulfasalazine dosage over weeks to months, patient tolerance has been improved.[118]

Oral mesalamine derivatives may impose a lower frequency of adverse effects as compared with sulfasalazine. Up to 80% to 90% of patients who are intolerant to sulfasalazine will tolerate oral mesalamine derivatives.[117] However, olsalazine may cause watery diarrhea in up to 25% of patients, often requiring drug discontinuation.[117]

Adverse reactions to corticosteroids are well recognized and may occur when corticosteroids are used for any indication. However, there is a greater potential for adverse effects when corticosteroids are used for the treatment of IBD because high doses must often be used for extended periods. The well-appreciated adverse effects of corticosteroids include hyperglycemia, hypertension, osteoporosis, acne, fluid retention, electrolyte disturbances, myopathies, muscle wasting, increased appetite, psychosis, and reduced resistance to infection. In addition, corticosteroid use may cause adrenocortical suppression. To minimize corticosteroid effects, clinicians have used alternate-day steroid therapy; however, some patients do not do well clinically on the days when no steroid is given. For most patients a single daily corticosteroid dose suffices, and divided daily doses are unnecessary. Another problem with corticosteroids is adrenal insufficiency after abrupt steroid withdrawal. This necessitates gradual tapering of steroid therapy for patients using these agents daily for more than 2 to 3 weeks.[117] Due to its lower bioavailability and lower potential for adverse effects, budesonide may be used as alternate steroid therapy in CD involving the ileum or right colon or may be substituted for prednisone in CD patients who are steroid dependent or require long-term therapy.[36,40,106]

Immunomodulators, such as azathioprine and mercaptopurine, have a significant potential for adverse reactions and have resulted in withdrawal rates in clinical trials of up to 20%.[59] Adverse events to thiopurines are typically divided into two groups, type A and type B.[59] Type A are dose related and include malaise, nausea, infectious complications, hepatitis, and myelosuppression. As mentioned earlier, the myelosuppression from azathioprine and mercaptopurine is related to a deficiency of TPMT with subsequent accumulation of toxic metabolites. Type B reactions are considered idiosyncratic and include fever, rash, arthralgia, and pancreatitis (3% to 15% of patients).[59,117] 6-Mercaptopurine causes adverse reactions similar to azathioprine; however, there are fewer reports of lymphomas with this agent. Some data suggest that mercaptopurine may be used successfully for patients who are intolerant to azathioprine.[119]

Most patients receiving metronidazole for CD tolerate the agent fairly well; however, mild adverse effects occur frequently. They commonly include nauseas, metallic taste, urticaria, and glossitis.[66,117] More serious effects that occur with long-term use include development of paresthesias and reversible peripheral neuropathy.[66,117] Other effects include a disulfiram-like reaction if alcohol is ingested in conjunction.

The TNF-α inhibitors may be associated with development of serious adverse effects and carry similar adverse profiles for the available agents. Infliximab use has been associated with infusion reactions. Premedication with acetaminophen, diphenhydramine, and possibly corticosteroids may reduce the incidence and severity of these reactions.[40,120,121] Due to administration via the subcutaneous route, adalimumab and certolizumab may be more associated with injection site reactions versus infusion-related reactions. Serum sickness has occurred for patients who received infliximab doses separated by a long period of time.[67,76,121] Autoimmune phenomena, such as lupus and hemolytic anemia, may also occur during infliximab therapy, as well as an increase in the incidence of adverse neurologic events such as optic neuritis and demyelinating syndrome.[120] Risk of hepatosplenic T-cell lymphoma may be increased with use of infliximab, particularly if used in combination with immunomodulators such as azathioprine. Young male patients appear to be at higher risk for development of lymphoma.[40,120,121] Infliximab may also cause worsening of heart failure and thus is contraindicated for patients with New York Heart Association Class III or IV heart failure.

All TNF-α inhibitors predispose patients to development of serious infections. Patients with clinically significant active infections should not receive TNF-α inhibitors. Sepsis and tuberculosis may occur because of the inhibition of TNF-protective mechanisms. Patients should receive a tuberculin skin test [purified protein derivative (PPD)] ORA QuantiFERON® test and a chest x-ray prior to initiating therapy to rule out undiagnosed tuberculosis.[67,121] Reactivation of hepatitis B may occur; thus, patients should also be screened for hepatitis B virus infection prior to initiating therapy.[121] Patients should also be screened for hepatitis C infection, although it does not appear that use of TNF-α inhibitors alter the disease course.[121] Lastly, use of natalizumab is associated with development of progressive multifocal leukoencephalopathy and is only available via the manufacturer's TOUCH prescribing program.[67] Patients receiving

natalizumab should be monitored for development of adverse neurologic events and undergo MRI of the brain should development of progressive multifocal leukoencephalopathy be suspected.

EVALUATION OF THERAPEUTIC OUTCOMES

The success of therapeutic regimens to treat IBD can be measured by patient-reported complaints, signs, and symptoms; by direct clinician examination (including endoscopy); by history and physical examination; by selected laboratory tests; and by quality-of-life measures. Evaluation of IBD severity is difficult because much of the assessment is subjective.[122] To create more objective measures, disease rating scales or indices have been created. The CD Activity Index (CDAI) is a commonly used scale, particularly for evaluation of patients during clinical trials.[123] The scale incorporates eight elements: (1) number of stools in the past 7 days, (2) sum of abdominal pain ratings from the past 7 days, (3) rating of general well-being in the past 7 days, (4) use of antidiarrheals, (5) body weight, (6) hematocrit, (7) finding of abdominal mass, and (8) a sum of extraintestinal symptoms present in the past week. Elements of this index provide a guide for those measures that may be useful in assessing the effectiveness of treatment regimens. A subsequent scale was developed specifically for Perianal CD, known as the *Perianal CD Activity Index* (PDAI).[122] The PDAI includes five items: presence of discharge, pain, restriction of sexual activity, type of perianal disease, and degree of induration.

Standardized assessment tools have also been constructed for UC.[124,125] Elements in these scales include (1) stool frequency, (2) presence of blood in the stool, (3) mucosal appearance (from endoscopy), and (4) physician's global assessment based on physical examination, endoscopy, and laboratory data.

Additional studies that are often useful include direct endoscopic examination of affected areas and/or radiocontrast studies. For patients with acute disease, assessment of fluid and electrolyte status is important, because these may be lost during diarrheal episodes. Other laboratory tests, such as serum albumin, transferrin, or other markers of visceral protein status as well as markers of inflammation (ESR or CRP), may be used.

Assessment of the IBD patient must include consideration of adverse drug effects. Because many of the agents used have a relatively high probability of causing adverse effects, particularly corticosteroids and other immunosuppressive agents, patient assessment should include collection of history and physical and laboratory data that are necessary to prevent or recognize adverse drug effects.

Finally, a patient quality-of-life assessment should be performed regularly.[122] Agents that appear clinically equivalent may differ substantially in resulting quality of life. Inquiry should be made regarding general well-being, emotional function, and social function. Social function may include assessment of the ability to perform routine daily functions and to maintain occupational activities, sexual function, and recreation. The most common tool used to assess quality of life is the Inflammatory Bowel Disease Questionnaire (IBDQ), a 32-item questionnaire that covers four disease dimensions: bowel function, emotional status, systemic symptoms, and social function.[122,125] The IBDQ has shown good correlation with the CDAI.[122] A shortened version has also been developed for use in the community practice setting.[125] A lesser used tool is the Rating Form of Inflammatory Bowel Disease Patient Concerns.[122]

Quality-of-life studies have been conducted with infliximab. To balance the exceptionally high cost of this therapy, CD patients who receive infliximab have improved quality of life, have fewer emergency room visits, have a reduced requirement for surgery, and are more likely to be employed.[126,127]

ABBREVIATIONS

6-MP: 6-mercaptopurine
6-TGN: 6-thioguanine
ATI: antibodies to infliximab
CD: Crohn's disease
CRP: C-reactive protein
ESR: erythrocyte sedimentation rate
HLA: human leukocyte antigen
IBD: inflammatory bowel disease
NSAID: nonsteroidal antiinflammatory drug
TPMT: thiopurine S-methyltransferase
TNF-α: tumor necrosis factor-alpha
UC: ulcerative colitis

CHAPTER 42

Nausea and Vomiting

CECILY V. DIPIRO AND ROBERT J. IGNOFFO

KEY CONCEPTS

1. Nausea and/or vomiting is often a part of the symptom complex for a variety of gastrointestinal, cardiovascular, infectious, neurologic, metabolic, or psychogenic processes.
2. Nausea or vomiting is caused by a variety of medications or other noxious agents.
3. The overall goal of treatment should be to prevent or eliminate nausea and vomiting regardless of etiology.
4. Treatment options for nausea and vomiting include drug and nondrug modalities such as relaxation, biofeedback, and self-hypnosis.
5. The primary goal with chemotherapy-induced nausea and vomiting (CINV) is to prevent nausea and/or vomiting. Optimal control of acute nausea and vomiting positively impacts the incidence and control of delayed and anticipatory nausea and vomiting.
6. The emetic risk of the chemotherapeutic regimen is the primary factor to consider when selecting prophylactic antiemetics for CINV.
7. Patients at high risk of vomiting should receive prophylactic antiemetics for postoperative nausea and vomiting.
8. Patients receiving single-exposure, high-dose radiation therapy to the upper abdomen or receiving total or hemibody irradiation, should receive prophylactic antiemetics for radiation-induced nausea and vomiting.

Nausea and vomiting are common complaints in individuals of all ages. (Disorders are discussed in Etiology section.) However, because of the variable etiologies of these problems, management can be quite simple or detailed and complex, essentially innocuous or associated with therapy-induced adverse reactions. This chapter provides an overview of nausea and vomiting, two multifaceted problems.

Nausea is usually defined as the inclination to vomit or as a feeling in the throat or epigastric region alerting an individual that vomiting is imminent. Vomiting is defined as the ejection or expulsion of gastric contents through the mouth and is often a forceful event. Either condition may occur transiently with no other associated signs or symptoms; however, these conditions also may be only part of a more complex clinical presentation.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

ETIOLOGY

1 Nausea and vomiting may be associated with a variety of conditions, including gastrointestinal (GI), cardiovascular, infectious, neurologic, or metabolic disease processes. Nausea and vomiting may be a feature of such conditions as pregnancy, or may follow operative procedures or administration of certain medications, such as those used in cancer chemotherapy. Psychogenic etiologies of these symptoms may be present, especially in young women with an underlying emotional disturbance. Anticipatory etiologies may be involved, such as in patients who have previously received cytotoxic chemotherapy. Table 42–1 lists specific etiologies associated with nausea and vomiting.[1]

The etiology of nausea and vomiting may vary with the age of the patient. For example, vomiting in the newborn during the first day of life suggests upper digestive tract obstruction or an increase in intracranial pressure. Other illnesses associated with vomiting in children include pyloric stenosis, duodenal ulcer, stress ulcer, adrenal insufficiency, septicemia, and diseases of the pancreas, liver, or biliary tree. 2 Drug-induced nausea and vomiting are of particular concern, especially with the increasing number of patients receiving cytotoxic treatment. A four-level classification system defines the risk for emesis with specific cytotoxic agents (Table 42–2).[2] Although some agents may have greater emetic risk than others, combinations of agents, high doses, clinical settings, psychological conditions, prior treatment experiences, and unusual stimulus of sight, smell, or taste may alter a patient's response to drug treatment. In this setting, nausea and vomiting may be unavoidable and some patients experience these problems so intensely that chemotherapy is postponed or discontinued.

Cancer patients undergoing chemotherapy may experience breakthrough nausea and/or vomiting despite receiving prophylactic antiemetics. Historically, breakthrough emesis occurs in 10% to 40% treated with modern-day antiemetics. Anticipatory nausea or vomiting (ANV) is believed to be a learned, conditioned, or psychological response to a poor outcome from a previous event. It may be triggered by tastes, odors, sights, thoughts, or anxiety associated with chemotherapy.[3] In the setting of optimal antiemetic prophylaxis, chemotherapy-induced ANV can occur in up to 10% and 20% of patients receiving chemotherapy but rarely occurs unless the patient has previously experienced post-treatment nausea or vomiting.[4,5] In addition to the emetic risk of various cytotoxic regimens, other common etiologies have been proposed for the development of nausea and vomiting in cancer patients (Table 42–3).[6,7]

TABLE 42-1 Specific Etiologies of Nausea and Vomiting

Gastrointestinal mechanisms
Mechanical obstruction
Gastric outlet obstruction
Small bowel obstruction
Functional gastrointestinal disorders
Gastroparesis
Nonulcer dyspepsia
Chronic intestinal pseudoobstruction
Irritable bowel syndrome
Organic gastrointestinal disorders
Peptic ulcer disease
Pancreatitis
Pyelonephritis
Cholecystitis
Cholangitis
Hepatitis
Acute gastroenteritis
Viral
Bacterial
Cardiovascular diseases
Acute myocardial infarction
Congestive heart failure
Radiofrequency ablation
Neurologic processes
Increased intracranial pressure
Migraine headache
Vestibular disorders
Metabolic disorders
Diabetes mellitus (diabetic ketoacidosis)
Addison disease
Renal disease (uremia)
Psychiatric causes
Psychogenic vomiting
Anxiety disorders
Anorexia nervosa
Therapy-induced causes
Cytotoxic chemotherapy
Radiation therapy
Theophylline preparations
Anticonvulsant preparations
Digitalis preparations
Opiates
Antibiotics
Volatile general anesthetics
Drug withdrawal
Opiates
Benzodiazepines
Miscellaneous causes
Pregnancy
Noxious odors
Operative procedures

TABLE 42-2 Emetic Risk of Intravenous Cytotoxic Agents

Emetic Risk (If No Prophylactic Medication is Administered)	Cytotoxic Agent (in Alphabetical Order)
High (>90%)	Carmustine
	Cisplatin
	Cyclophosphamide ≥1,500 mg/m^2
	Dacarbazine
	Dactinomycin
	Mechlorethamine
	Streptozotocin
Moderate (30%–90%)	Carboplatin
	Cytarabine >1 g/m^2
	Cyclophosphamide <1,500 mg/m^2
	Daunorubicin
	Doxorubicin
	Epirubicin
	Idarubicin
	Ifosfamide
	Irinotecan
	Oxaliplatin
	Procarbazine
Low (10%–30%)	Bortezomib
	Capecitabine
	Cetuximab
	Cytarabine ≤1 g/m^2
	Docetaxel
	Erlotinib
	Etoposide
	Fluorouracil
	Gemcitabine

Data from Prevention of chemotherapy and radiotherapy-induced emesis. Results of the 2004 Perugia International Antiemetic Consensus Conference. Ann Oncol 2006;17:20–28, by permission of Oxford University.

PATHOPHYSIOLOGY

The three consecutive phases of emesis include nausea, retching, and vomiting. Nausea, the imminent need to vomit, is associated with gastric stasis and may be considered a separate and singular symptom. Retching is the labored movement of abdominal and thoracic muscles before vomiting. The final phase of emesis is vomiting, the forceful expulsion of gastric contents caused by GI retroperistalsis. The act of vomiting requires the coordinated contractions of the abdominal muscles, pylorus, and antrum, a raised gastric cardia, diminished lower esophageal sphincter pressure, and esophageal dilatation.[8] Vomiting should not be confused with regurgitation, an act in which the gastric or esophageal contents rise to the pharynx because of pressure differences caused by, for example, an incompetent lower esophageal sphincter. Accompanying autonomic symptoms of pallor, tachycardia, and diaphoresis account for many of the distressing feelings associated with emesis.

Vomiting is triggered by afferent impulses to the vomiting center, a nucleus of cells in the medulla. Impulses are received from sensory centers, which include the chemoreceptor trigger zone (CTZ), cerebral cortex, and visceral afferents from the pharynx and GI tract. These afferent impulses are integrated by the vomiting center, resulting in efferent impulses to the salivation center, respiratory center, and the pharyngeal, GI, and abdominal muscles, leading to vomiting.

TABLE 42-4 Presentation of Nausea and Vomiting

General
Depending on severity of symptoms, patients may present in mild to severe distress

Symptoms
Simple: Self-limiting, resolves spontaneously and requires only symptomatic therapy
Complex: Not relieved after administration of antiemetics; progressive deterioration of patient secondary to fluid–electrolyte imbalances; usually associated with noxious agents or psychogenic events

Signs
Simple: Patient complaint of queasiness or discomfort
Complex: Weight loss; fever; abdominal pain

Laboratory tests
Simple: None
Complex: Serum electrolyte concentrations; upper/lower GI evaluation

Other information
Fluid input and output
Medication history
Recent history of behavioral or visual changes, headache, pain, or stress
Family history positive for psychogenic vomiting

The CTZ, located in the area postrema of the fourth ventricle of the brain, is a major chemosensory organ for emesis and is usually associated with chemically induced vomiting. Because of its location, bloodborne and cerebrospinal fluid toxins have easy access to the CTZ. Therefore, cytotoxic agents primarily stimulate this area rather than the cerebral cortex and visceral afferents. Similarly, pregnancy-associated vomiting probably occurs through stimulation of the CTZ.

Numerous neurotransmitter receptors are located in the vomiting center, CTZ, and GI tract, including cholinergic, histaminic, dopaminergic, opiate, serotonergic, neurokinin, and benzodiazepine receptors. Chemotherapeutic agents, their metabolites, or other emetic compounds theoretically trigger the process of emesis through stimulation of one or more of these receptors. Effective antiemetics are able to antagonize or block the emetogenic receptors.

CLINICAL PRESENTATION

Because it is impossible to discuss all clinical settings in which the presence of nausea and vomiting might be a pertinent finding, these processes are presented in Table 42–4 as they might occur together, and also as *simple* or *complex* in presentation.

TREATMENT

DESIRED OUTCOME

3 The overall goal of antiemetic therapy is to prevent or eliminate nausea and vomiting. This should be accomplished without adverse effects or with clinically acceptable adverse effects. Although this goal may be accomplished easily in patients with simple nausea and vomiting, patients with more complex problems require greater assistance. In addition to these clinical goals, appropriate cost issues should be considered, particularly in the management of chemotherapy-induced and postoperative nausea and vomiting.

GENERAL APPROACH TO TREATMENT

4 Treatment options for nausea and vomiting include drug and nondrug modalities. The treatment of nausea and vomiting is quite varied depending on the associated medical situation. Even though a number of potentially effective measures are available, most patients receive a medication at some point in their care. For simple nausea and vomiting, patients may choose to do nothing or to select from a variety of nonprescription drugs. As symptoms become worse or are associated with more serious medical problems, patients are more likely to benefit from prescription antiemetic drugs. When prescribed according to reliable clinical information, these agents often provide acceptable relief; however, some patients will never be totally free of symptoms. This lack of relief is most disabling when it is associated with an unresolved medical problem or when the necessary therapy for this condition is the cause of the nausea or vomiting, as in the case of patients who are receiving chemotherapy of moderate or high emetic risk.

NONPHARMACOLOGIC MANAGEMENT

Nonpharmacologic management of nausea and vomiting involves the use of a variety of dietary, physical, or psychological strategies that are consistent with the etiology of nausea and vomiting. For patients with simple complaints, perhaps resulting from excessive or disagreeable food or beverage consumption, avoidance or moderation in dietary intake may be preferable. Patients suffering symptoms of systemic illness may improve dramatically as their underlying condition resolves. Finally, patients in whom these symptoms result from labyrinthine changes produced by motion may benefit quickly by assuming a stable physical position.

Nonpharmacologic interventions are classified as behavioral interventions and include relaxation, biofeedback, self-hypnosis, cognitive distraction, guided imagery, acupuncture, and systematic desensitization.[9,10] The reader is referred to references 11 to 13 for a more complete discussion on nonpharmacological strategies.

PHARMACOLOGIC THERAPY

4 Although many approaches to the treatment of nausea and vomiting have been suggested, antiemetic drugs (nonprescription and prescription) are most often recommended. These agents represent a variety of pharmacologic and chemical classes, as well as dosage regimens and routes of administration. With so many treatment possibilities available, factors that enable the clinician to

TABLE 42-5 Common Antiemetic Preparations and Adult Dosage Regimens

Drug	Adult Dosage Regimen	Dosage Form/Route	Availability
Antacids			
Antacids (various)	15–30 mL every 2–4 h prn	Liquid/oral	OTC
Antihistaminic–anticholinergic agents			
Cyclizine (Marezine)	50 mg before departure; may repeat in 4–6 h prn	Tab	OTC
Dimenhydrinate (Dramamine)	50–100 mg every 4–6 h prn	Tab, chew tab, cap	OTC
Diphenhydramine (Benadryl)	25–50 mg every 4–6 h prn	Tab, cap, liquid	Rx/OTC
	10–50 mg every 2–4 h prn	IM, IV	
Hydroxyzine (Vistaril, Atarax)	25–100 mg every 4–6 h prn	IM (unlabeled use)	Rx
Meclizine (Bonine, Antivert)	12.5–25 mg 1 h before travel; repeat every 12–24 h prn	Tab, chew tab	Rx/OTC
Scopolamine (Transderm Scop)	1.5 mg every 72 h	Transdermal patch	Rx
Trimethobenzamide (Tigan)	300 mg 3–4 times daily	Cap	Rx
	200 mg 3–4 times daily	IM	
Benzodiazepines			
Alprazolam (Xanax)	0.5–2 mg three times daily prior to chemotherapy	Tab	Rx (C-IV)
Lorazepam (Ativan)	0.5–2 mg on night before and morning of chemotherapy	Tab	Rx (C-IV)
Butyrophenones			
Haloperidol (Haldol)	1–5 mg every 12 h prn	Tab, liquid, IM, IV	Rx
Droperidol (Inapsine)[a]	2.5 mg; additional 1.25 mg may be given	IM, IV	Rx
Cannabinoids			
Dronabinol (Marinol)	5–15 mg/m^2 every 2–4 h prn	Cap	Rx (C-III)
Nabilone (Cesamet)	1–2 mg twice daily	Cap	Rx (C-II)
Histamine (H_2) antagonists			
Cimetidine (Tagamet HB)	200 mg twice daily prn	Tab	OTC
Famotidine (Pepcid AC)	10 mg twice daily prn	Tab	OTC
Nizatidine (Axid AR)	75 mg twice daily prn	Tab	OTC
Ranitidine (Zantac 75)	75 mg twice daily prn	Tab	OTC
5-hydroxytryptamine-3 receptor antagonists (see Tables 42–6 for CINV dosing and 42–8 for PONV dosing)			
Miscellaneous agents			
Metoclopramide (Reglan), for delayed CINV	20–40 mg 3–4 daily	Tab	Rx
Olanzapine (Zyprexa)	2.5–5 mg twice daily	Tab	Rx
Phenothiazines			
Chlorpromazine (Thorazine)	10–25 mg every 4–6 h prn	Tab, liquid	Rx
	25–50 mg every 4–6 h prn	IM, IV	
Prochlorperazine (Compazine)	5–10 mg 3–4 daily prn	Tab, liquid	Rx
	5–10 mg every 3–4 h prn	IM	
	2.5–10 mg every 3–4 h prn	IV	Rx
	25 mg twice daily prn	Supp	Rx
Promethazine (Phenergan)	12.5–25 mg every 4–6 h prn	Tab, liquid, IM, IV, supp	Rx

C-II, C-III, C-IV, controlled substance schedule 2, 3, and 4, respectively; cap, capsule; chew tab, chewable tablet; CINV, chemotherapy-induced nausea and vomiting; liquid, oral syrup, concentrate, or suspension; OTC, nonprescription; PONV, postoperative nausea and vomiting; Rx, prescription; supp, rectal suppository; tab, tablet.

[a]See text for current warnings.

discriminate among various choices include (a) the suspected etiology of the symptoms; (b) the frequency, duration, and severity of the episodes; (c) the ability of the patient to use oral, rectal, injectable, or transdermal medications; and (d) the success of previous antiemetic medications. Please see Table 42–5 for dosing information of commonly available antiemetic preparations.

The treatment of simple nausea and vomiting usually requires minimal therapy. For these symptoms, patients may choose from a lengthy list of nonprescription products. Both nonprescription and prescription drugs useful in the treatment of simple nausea and vomiting are usually effective in small, infrequently administered doses. Side effects and toxic effects in these settings are also usually minimal. Although suitable for occasional simple nausea and vomiting, nonprescription agents are often abandoned by the patient as symptoms continue or become progressively worse. As the patient's condition warrants, prescription medications may be chosen, either as single-agent therapy or in combination.

The management of complex nausea and vomiting, for example, in patients who are receiving cytotoxic chemotherapy, may require combination therapy. In combination regimens, the goal is to achieve symptomatic control through administration of agents with different pharmacologic mechanisms of action.

Antacids

Patients who are experiencing simple nausea and vomiting may use various antacids. In this setting, single or combination nonprescription antacid products, especially those containing magnesium hydroxide, aluminum hydroxide, and/or calcium carbonate, may provide sufficient relief, primarily through gastric acid neutralization.

Common antacid regimens for the relief of acute or intermittent nausea and vomiting include one or more 15 to 30 mL doses of single- or multiple-agent products. Potential adverse effects from antacids are usually related to the presence of magnesium, aluminum, or calcium salts. Specifically, osmotic diarrhea from magnesium and constipation from aluminum or calcium salts may be of concern to patients, particularly those self-medicating with

high or frequently administered antacid doses. Generally, however, when used occasionally for acute episodic relief of nausea and vomiting, antacids do not produce serious toxicities.

Antihistamine–Anticholinergic Drugs

Antiemetic drugs from the antihistaminic–anticholinergic category appear to interrupt various visceral afferent pathways that stimulate nausea and vomiting and may be appropriate in the treatment of simple nausea and vomiting. Adverse reactions associated with the use of the antihistaminic–anticholinergic agents primarily include drowsiness, confusion, blurred vision, dry mouth, and urinary retention, and possibly tachycardia, particularly in elderly patients. Also, as doses are increased or are more frequently administered, patients with narrow-angle glaucoma, prostatic hyperplasia, or asthma are at greater risk of complications from the anticholinergic effects of these drugs.

Benzodiazepines

Since nausea and vomiting are often associated with chemotherapy, radiotherapy, and surgery, anticipatory anxiety may occur prior to these therapies and may exacerbate symptoms. Benzodiazepines may be useful in this setting.

Benzodiazepines are relatively weak antiemetics and are primarily used to prevent anxiety or ANV in patients receiving highly emetogenic chemotherapy. They are also useful against akathisia associated with metoclopramide therapy. Both alprazolam and lorazepam are used as adjuncts to other antiemetics in patients treated with cisplatin-containing regimens. Lorazepam significantly reduced the incidence of ANV in cisplatin-treated patients. Lorazepam caused both mild sedation and amnesia.[14] Alprazolam is usually given orally and has an onset of about 60 minutes, while lorazepam is given orally or sublingually, which has a more rapid onset.

Buterophenones

Two buterophenone compounds that have antiemetic activity are haloperidol and its congener droperidol; both block dopaminergic stimulation of the CTZ. Although each agent is effective in relieving nausea and vomiting, haloperidol is not considered first-line therapy for uncomplicated nausea and vomiting but has been used in palliative care situations.[15] The current labeling of droperidol recommends that all patients should undergo a 12-lead electrocardiogram prior to administration, followed by cardiac monitoring for 2 to 3 hours after administration because of the possibility of the development of potentially fatal QT prolongation and/or torsade de pointes.[16] The clinical use of droperidol has effectively ceased outside of clinical trials in anesthesia.

Cannabinoids

Cannabinoids have complex effects on the central nervous system (CNS) and their effects at receptors in neural tissues may explain efficacy in chemotherapy-induced nausea and vomiting (CINV). Oral dronabinol and nabilone are one of several therapeutic options when CINV is refractory to other antiemetics; they are not indicated as first-line agents.

Chemotherapy use with over 1,300 patients in 30 randomized, controlled trials from 1975 to 1996 was analyzed to quantify the antiemetic efficacy and adverse effects of several cannabinoids.[17] Oral nabilone, oral dronabinol, and intramuscular levonantradol were compared with conventional antiemetics (prochlorperazine, metoclopramide, chlorpromazine, thiethylperazine, haloperidol, domperidone, and alizapride) or placebo. Across all trials, cannabinoids were slightly more effective than active comparators and placebo when the chemotherapy regimen was of moderate emetogenic potential, and patients preferred them. No dose–response relationships were evident to the authors. Side effects included euphoria, drowsiness, sedation, somnolence, dysphoria, depression, hallucinations, and paranoia.

Corticosteroids

Corticosteroids have demonstrated antiemetic efficacy since the initial recognition that patients who received prednisone as part of their Hodgkin disease protocol appeared to develop less nausea and vomiting than did those patients who were treated with protocols that excluded this agent. Methylprednisolone has also been used as a component of an antiemetic regimen, but the majority of trials have included dexamethasone. The site and mechanism of action of corticosteroids for CINV is unknown.

Dexamethasone is the most commonly used corticosteroid in the management of chemotherapy-induced and postoperative nausea and vomiting (PONV), either as a single agent or in combination with 5-hydroxytryptamine-3 receptor antagonists (5-HT_3-RA). For CINV, dexamethasone is effective in the prevention of both cisplatin-induced acute emesis and when used alone or in combination for the prevention of delayed nausea and vomiting associated with CINV.[18–21] Corticosteroids affect almost every organ system. Insomnia, gastrointestinal symptoms, agitation, and appetite stimulation are some of the more common side effects reported in this patient population. For patients with simple nausea and vomiting, steroids are not indicated and may be associated with unacceptable risks.

H_2-Receptor Antagonists

Histamine$_2$-receptor antagonists work by decreasing gastric acid production and are used to manage simple nausea and vomiting associated with heartburn or gastroesophageal reflux. Except for potential drug interactions with cimetidine, these agents cause few side effects when used for episodic relief.

5-Hydroxytryptamine-3 Receptor Antagonists

5-HT_3-RAs block presynaptic serotonin receptors on sensory vagal fibers in the gut wall, effectively blocking the acute phase of CINV. These agents do not completely block the acute phase of CINV and are less efficacious in preventing the delayed phase, but they are the standard of care in the management of CINV, PONV, and radiation-induced nausea and vomiting (RINV). Issues involved in the use of dolasetron, granisetron, ondansetron, and palonosetron are reviewed in detail in the sections that follow. The most common side effects associated with these agents are constipation, headache, and asthenia.

Metoclopramide

Metoclopramide, a procainamide congener, provides significant antiemetic effects by blocking the dopaminergic receptors centrally in the CTZ. Metoclopramide increases lower esophageal sphincter tone, aids gastric emptying, and accelerates transit through the small bowel, possibly through the release of acetylcholine. Metoclopramide is used for its antiemetic properties in patients with diabetic gastroparesis and with dexamethasone for prophylaxis of delayed CINV. Its use as prophylaxis for acute chemotherapy-induced nausea and vomiting was supplanted by the introduction of the 5-HT_3-RAs in the early 1990s. These agents have greater efficacy and decreased toxicity compared with metoclopramide in patients who are receiving cisplatin-based regimens.[22,23]

Olanzapine

Olanzapine is an antipsychotic that blocks several neurotransmitters including dopamine at D_2 and 5-HT_3-RA. Use of olanzapine,

in combination with palonosetron and dexamethasone, effectively prevented acute CINV, while continued monotherapy with olanzapine prevented most cases of delayed nausea and vomiting in patients receiving moderately and highly emetogenic chemotherapy in a single-arm, phase 2 clinical trial in 40 patients.[24] The National Comprehensive Cancer Network (NCCN) antiemesis practice guideline includes olanzapine as one of many options in patients who experience breakthrough nausea and/or vomiting following prophylaxis for CINV.[25] Sedation is the most common side effect with olanzapine.

Phenothiazines

Phenothiazines have been the most widely prescribed antiemetic agents and appear to block dopamine receptors, most likely in the CTZ. Phenothiazines are marketed in an array of dosage forms, none of which appears to be more efficacious than another. These agents may be most practical for long-term treatment and are inexpensive in comparison with newer drugs. Rectal administration is a reasonable alternative in patients in whom oral or parenteral administration is not feasible.

Phenothiazines are most useful in adult patients with simple nausea and vomiting. Intravenous prochlorperazine provided quicker and more complete relief with less drowsiness than intravenous promethazine in adult patients treated in an emergency department for nausea and vomiting associated with uncomplicated gastritis or gastroenteritis.[26] There are numerous potential side effects with these medications, including extrapyramidal reactions, hypersensitivity reactions with possible liver dysfunction, bone marrow aplasia, and excessive sedation.

Substance P/Neurokinin 1 Receptor Antagonists

Substance P is a peptide neurotransmitter in the neurokinin (NK) family whose preferred receptor is the NK_1 receptor.[27] The acute phase of CINV is believed to be mediated by both serotonin and substance P, whereas substance P is believed to be the primary mediator of the delayed phase. Aprepitant is the first substance P/NK_1 receptor antagonist in clinical use; others are in development. The efficacy of aprepitant was demonstrated in patients receiving high-dose cisplatin-based chemotherapy[20,21] and in patients receiving doxorubicin and cyclophosphamide,[28] a regimen of moderate to high emetic risk. The three-drug regimen of aprepitant, dexamethasone, and ondansetron provided improved protection from vomiting for the 5 days after chemotherapy administration as compared with the combination of dexamethasone and ondansetron.

Aprepitant has the potential for numerous drug interactions because it is a substrate, moderate inhibitor, and an inducer of cytochrome isoenzyme CYP3A4 and an inducer of CYP2C9. Aprepitant can increase serum concentrations of many drugs metabolized by CYP3A4, including docetaxel, paclitaxel, etoposide, irinotecan, ifosfamide, imatinib, vinorelbine, vincristine, and vinblastine. In clinical studies, aprepitant was concomitantly administered with etoposide, vinorelbine, or paclitaxel, with no adjustment in the doses of these agents to account for potential drug interactions. The efficacy of oral contraceptives may be reduced when given with aprepitant. Concomitant administration with warfarin may result in a clinically significant decrease in the international normalized ratio.[29] The dose of oral dexamethasone should be reduced 50% when coadministered with aprepitant, because of the 2.2-fold increase in observed area under the plasma-concentration-versus time curve.[30] Aprepitant is not approved for use in children.

Fosaprepitant, an injectable form of aprepitant, has been approved by the FDA as an intravenous substitute for oral aprepitant on day 1 of the standard 3-day CINV prevention regimen, with oral aprepitant administered on days 2 and 3.[31]

CHEMOTHERAPY-INDUCED NAUSEA AND VOMITING

There are five categories of CINV: acute, delayed, anticipatory, breakthrough, and refractory. 5 Nausea and vomiting that occurs within 24 hours of chemotherapy administration is defined as acute, whereas when it starts more than 24 hours after chemotherapy administration, it is defined as delayed. The primary goal with CINV is to *prevent* nausea and/or vomiting. Optimal control of acute nausea and vomiting impacts positively on the incidence and control of delayed and anticipatory nausea and vomiting.[32]

Emesis occurring during previous chemotherapy predisposes for the risk of developing ANV.[4] Breakthrough nausea and vomiting is defined as emesis occurring despite prophylactic administration of antiemetics, requiring use of rescue antiemetics. Poor response to multiple antiemetic regimens is defined as refractory nausea and vomiting.

Clinical practice guidelines for the use of antiemetics in CINV have been published.[2,25,33] Despite the demonstrated improvement in outcomes with the use of these practice guidelines, they are underutilized by a high percentage of practitioners.[34] Furthermore, product availability and recommended doses are often institution-specific and may vary considerably from the doses listed in Table 42–6.

Factors to consider when selecting an antiemetic for CINV include the following:

- The emetic risk of the chemotherapy agent or regimen (see Table 42–2)
- Patient-specific factors
- Patterns of emesis after administration of specific chemotherapy agents or regimens

Prophylaxis of Acute CINV

6 The emetic risk of the chemotherapeutic agent (see Table 42–2) is the primary factor to consider when deciding whether to administer prophylactic agents and which antiemetic(s) to select. Table 42–6 summarizes recommendations from version 4 of the 2009 NCCN antiemetic guidelines.[25] Antiemetic guidelines published by other groups are in overall agreement with the NCCN guidelines.

Patients receiving chemotherapy that is classified as being of high emetic risk should receive a combination of three antiemetic drugs on the day of chemotherapy administration (day 1) including a $5\text{-}HT_3$-RA (e.g., dolasetron, granisetron, ondansetron, or palonosetron) + dexamethasone + an NK_1 receptor antagonist (e.g., aprepitant). Patients receiving regimens that are classified as moderate emetic risk should receive a two-drug combination antiemetic regimen containing a $5\text{-}HT_3$-RA + dexamethasone on day 1. The exception to this is patients who are receiving an anthracycline plus cyclophosphamide and select patients receiving other chemotherapies of moderate emetic risk, for example, carboplatin, cisplatin, doxorubicin, epirubicin, ifosfamide, irinotecan or methotrexate; these patients should receive the triple-drug combination described for regimens of high emetic risk.

For chemotherapy regimens that are low emetic risk, dexamethasone or any of the following: prochlorperazine, metoclopramide, and/or diphenhydramine, and/or lorazepam alone is recommended for prophylaxis.[25] When equivalent doses are used for the prevention of acute emesis, all $5\text{-}HT_3$-RAs are considered to be of

TABLE 42-6 Dosage Recommendations for CINV for Adult Patients

Emetic Risk	Prophylaxis of Acute Phase of CINV (One Dose Administered Prior to Chemotherapy)	Prophylaxis of Delayed Phase of CINV
High (including the AC regimen[a])	5-HT_3 receptor antagonists (5-HT_3-RA):	
	Dolasetron 100 mg orally or 100 mg IV or 1.8 mg/kg IV	
	Granisetron 2 mg orally or 1 mg IV or 0.01 mg/kg IV or 34.3 mg transdermal patch	
	Ondansetron 16–24 mg orally or 8–12 mg IV (maximum 32 mg)	
	Palonosetron 0.25 mg IV	
	and Dexamethasone 12 mg orally or IV	Dexamethasone 8–12 mg orally days 2–4
	and Aprepitant 125 mg orally or Fosaprepitant 115 mg IV	Aprepitant 80 mg orally days 2 and 3 after chemotherapy
Moderate	5-HT_3-RA:	
	Dolasetron 100 mg orally or 100 mg IV or 1.8 mg/kg IV	5-HT_3-RA : Dolasetron 100 mg orally daily[b]
	Granisetron 2 mg orally or 1 mg IV or 0.01 mg/kg IV or 34.3 mg transdermal patch	Granisetron 1–2 mg orally daily[b]
	Ondansetron 16–24 mg orally or 8–12 mg IV (max. 32 mg)	Ondansetron 8 mg orally daily or twice daily[b]
	Palonosetron 0.25 mg IV	
	Palonosetron 0.5 mg orally	
	and Dexamethasone 8–12 mg orally or IV	Dexamethasone 8–12 mg orally daily[b]
	and in select patients[c] Aprepitant 125 mg orally or Fosaprepitant 115 mg IV	Aprepitant 80 mg orally days 2 and 3 if used on day 1
Low	Dexamethasone 8–12 mg orally or IV	None
Minimal	None	None

[b]For 2–3 days following chemotherapy.
[c]Patients receiving other chemotherapies of moderate emetic risk, for example, carboplatin, cisplatin, doxorubicin, epirubicin, ifosfamide, irinotecan, or methotrexate.
Doses included in the above table reflect the recommendations from published guidelines (references 2, 25, 33). These doses may differ from manufacturer labeling; they reflect the consensus of the guideline participants.
CINV, chemotherapy-induced nausea and vomiting.

equivalent efficacy and safety. When available in both oral and intravenous dosage forms, oral agents are equally effective as intravenous products. The decision as to which 5-HT_3-RA to use should be based on patient-specific factors and cost.

Prophylaxis of Delayed CINV

Management of delayed CINV has historically challenged practitioners. The best strategy for preventing delayed CINV (nausea and/or vomiting occurring 24 or more hours after chemotherapy) is to control acute CINV and provide adequate prophylaxis for delayed CINV.[35] Aprepitant, dexamethasone, and metoclopramide are effective in preventing delayed CINV, whereas 5-HT_3-RAs are inconsistent.[27] However, palonosetron controlled delayed emesis more effectively than granisetron, suggesting that another 5-HT_3-RA should not be prescribed as a rescue medication when palonosetron is given prophylactically for acute CINV.[36]

Patients receiving cisplatin and other agents are at highest risk for experiencing delayed CINV. The addition of aprepitant in the recommended three-drug combination on the day of cisplatin administration and additional doses of aprepitant and dexamethasone on days two and three after cisplatin administration improved the control of delayed vomiting as compared with patients who received dexamethasone alone postchemotherapy (51% vs 72%).[20,21] Use of aprepitant also decreased delayed CINV in patients receiving an anthracycline plus cyclophosphamide, as compared with twice-daily ondansetron (49% vs 55%).[28] Current practice guidelines recommend administration of aprepitant and dexamethasone on days 2 and 3 and dexamethasone with or without lorazepam on day 4.[2,25]

The incidence of delayed CINV following chemotherapy with agents of moderate emetic risk is less well defined. The current NCCN recommendation is to give aprepitant or any of the following: dexamethasone, a 5-HT_3-RA, and/or lorazepam and/or a histamine-2 blocker or a proton pump inhibitor on days 2 and 3.[25] The American Society of Clinical Oncology (ASCO) and Multinational Association of Supportive Care in Cancer (MASCC) practice guidelines do not include aprepitant on days 2 and 3.

A second-generation 5-HT_3-RA, palonosetron, has a prolonged serum half-life and higher receptor binding affinity that may offer another option for prophylaxis of delayed CINV. Palonosetron given once every 7 days protected more patients from delayed emesis than either ondansetron or dolasetron in adult patients receiving chemotherapy of moderate emetic risk.[37–39] Subsequently, a large randomized, blinded study in patients receiving chemotherapy of high emetic risk showed that palonesetron plus dexamethasone was not inferior to granisetron plus dexamethasone for controlling acute CINV but was superior for delayed CINV.[36] Palonosetron may also be better than ondansetron in patients receiving multi-day chemotherapy, but a larger randomized, prospective trial is needed to substantiate the finding of a recent study.[40]

Treatment of Anticipatory Nausea and Vomiting

ANV is more difficult to control than acute or delayed CINV. A key principle in the treatment of ANV is that effective management of delayed CINV or ANV requires adequate control of acute CINV.[41] In addition, ANV may be prevented with behavioral therapy or pharmacotherapy.[42] The benzodiazepines, lorazepam and alprazolam, are effective in preventing ANV and improve outcomes in both acute and delayed emesis.

Treatment of Breakthrough CINV

Breakthrough nausea and/or vomiting occurs in 10% to 40% of patients receiving chemotherapy despite the use of multiagent prophylaxis.[32] All patients receiving chemotherapy should be prescribed antiemetics for rescue of breakthrough nausea and vomiting. Rescue medications used in adult patients include prochlorperazine, promethazine, lorazepam, metoclopramide, haloperidol, benzodiazepines such as lorazepam, 5-HT_3-RAs, dexamethasone, and cannabinoids such as dronabinol or olanzapine.[25,43]

Around-the-clock dosing of rescue antiemetics should be considered rather than as-needed administration. The choice of agent should be based on patient-specific factors, including potential adverse drug reactions and cost. Chlorpromazine, lorazepam, and dexamethasone are recommended for pediatric patients.[44]

Treatment of Refractory Nausea and Vomiting

The general approach to the management of refractory CINV is to upgrade the antiemetic strategy to the next level of prophylaxis or to add breakthrough antiemetics to the regimen.[45] Some patients will experience nausea and vomiting despite optimal acute and delayed prophylaxis and failure of rescue antiemetics. Addition of another agent from a different pharmacologic class is recommended and routes other than the oral route may be required. Agents such as corticosteroids, haloperidol, olanzapine, and nabilone in alternating schedules or by alternating routes are recommended.[25]

Prophylaxis of Anticipatory Nausea and Vomiting

As stated earlier, ANV rarely occurs unless the patient has previously experienced post-treatment nausea or vomiting. ANV may also be prevented with prophylactic pharmacotherapy using benzodiazepines the night before and morning of chemotherapy. A large observational study done after the introduction of 5-HT_3-RAs in patients receiving granisetron as antiemetic therapy evaluated ANV as an outcome.[7] An incidence of anticipatory nausea was observed in 10% and anticipatory vomiting in 2% of patients, which is substantially lower than reported prior to the application of effective antiemetic regimens.[46]

CLINICAL CONTROVERSY

The prevention of CINV in patients receiving multi-day chemotherapy is complicated by the overlap of acute and delayed emesis after the first day of chemotherapy. There are few studies and a lower complete control rate using standard antiemetic prophylaxis for patients receiving multi-day chemotherapy regimens.[47] While acute emesis can be controlled adequately, delayed emesis occurs in 50% or more of patients. Agents such as palonosetron, aprepitant, dexamethasone, and olanzapine are effective for both acute and delayed emesis and may have the greatest potential for success in multiday chemotherapy regimens. While the latest NCCN guidelines provide suggestions in this setting, further research is necessary before definitive recommendations can be made.

POSTOPERATIVE NAUSEA AND VOMITING

Postoperative nausea and vomiting (PONV) in adults complicates surgical procedures for approximately 25% to 30% of patients undergoing anesthesia.[48] PONV usually occurs within 24 hours after anesthesia, with the highest incidence during the first 2 hours. Most patients undergoing an operative procedure do not require preoperative prophylactic antiemetic therapy and universal PONV prophylaxis is not cost-effective. Table 42–7 summarizes the risk factors for PONV. The use of a risk assessment tool can improve emetic outcomes in patients undergoing surgery by identifying the patients most likely to benefit from prophylaxis.[49]

Adherence to consensus guidelines for prophylaxis and treatment of PONV decreases emetic episodes.[50,51] In addition to using prophylactic antiemetics in high-risk patients, other strategies include using regional rather than systemic anesthesia, propofol, and hydration, as well as avoiding nitrous oxide, volatile anesthetics, and opioids. Total intravenous anesthesia reduced the risk of PONV similar to the prophylactic administration of a single antiemetic.[52]

TABLE 42-7 Risk Factors for Postoperative Nausea and Vomiting (PONV)

Factors unrelated to anesthesia
History of motion sickness
Metabolic factors:
Uremia
Diabetes mellitus
Electrolyte disturbances
Patient-related factors
Age
Female gender (2 to 3 times greater incidence of PONV versus males)
Nonsmoker
History of PONV or motion sickness (3-fold increase in incidence of PONV)
Hydration status
Factors related to anesthesia
Use of volatile anesthetics
Nitrous oxide
Use of opioids (intraoperative or postoperative)
Factors related to surgery
Operative site (higher incidence of PONV after eye, oral, plastic, ear, nose and throat, head and neck, gynecological, obstetric, laparoscopic, and abdominal procedures)
Duration of surgery

Adapted from Kovac[48] and Gan et al.[50]

Prophylaxis of PONV

The most important independent predictors for PONV are female, nonsmoking, a history of PONV or motion sickness, and use of postoperative opiods. A simplified risk model allows clinicians to estimate the risk for PONV among patient groups.[49] Patients with 0 or 1 of these 4 risk factors present are at lowest risk (10–20%) and those with 3 or 4 risk factors are at highest risk for PONV (60–80%). Moderate risk is defined by this model as the presence of 2 risk factors. 7 Although the optimal management of PONV is not known, patients at highest risk of vomiting should receive prophylactic antiemetics. Patients at low risk for PONV are unlikely to benefit from prophylaxis and may potentially experience adverse reactions from the medications.

Patients at moderate risk for PONV should receive one or two prophylactic antiemetics, and those at high risk should receive two prophylactic antiemetic agents from different classes.[50,52] Optimal dosing of agents used in combination has not been determined. When the different combinations were compared, no differences were found between 5-HT_3-RA plus droperidol; 5-HT_3-RA plus dexamethasone; and droperidol plus dexamethasone.[53]

Cyclizine, dexamethasone, dolasetron, droperidol, granisetron, metoclopramide, ondansetron, tropisetron, scopolamine, and palonosetron are as effective as placebo for the prophylaxis of PONV.[54–56] Table 42–8 summarizes the doses for prophylactic antiemetics from the consensus guidelines.[50]

Dexamethasone is an effective, inexpensive prophylactic agent when administered either alone or in combination with other antiemetic drugs before the induction of anesthesia.[52,54,57] Although droperidol is one of the most effective agents for PONV prophylaxis, concerns about the development of torsade de pointes severely limit its use.[58] With equivalent efficacy and safety profiles, acquisition cost was the primary factor that differentiated the 5-HT_3-RAs from each other.[50] 5-HT_3-RAs appear to be most effective when given at the end of surgery.

The NK_1 antagonist aprepitant was approved for the prevention of PONV at a dose of 40 mg given orally within 3 hours prior to induction of anesthesia.[29] Aprepitant is equivalent to ondansetron 4 mg IV in the incidence of nausea and reducing the need for rescue in the 24 hours after surgery, but was significantly better than ondansetron for preventing vomiting in the 24 and 48 hours after surgery.[59]

TABLE 42-8 Recommended Prophylactic Doses of Selected Antiemetics for Postoperative Nausea and Vomiting in Adults and Postoperative Vomiting in Children

Drug	Adult Dose	Pediatric Dose (IV)	Timing of Dose[a]
Aprepitant[b]	40 mg orally	Not labeled for use in pediatrics	Within 3 h prior to induction
Dexamethasone	4–5 mg IV	150 mcg/kg up to 5 mg	At induction
Dimenhydrinate	1 mg/kg IV	0.5 mg/kg up to 25 mg	Not specified
Dolasetron	12.5 mg IV	350 mcg/kg up to 12.5 mg	At end of surgery
Droperidol[d]	0.625–1.25 mg IV	10–15 mcg/kg up to 1.25 mg	At end of surgery
Granisetron	0.35–1.5 mg IV	40 mcg/kg up to 0.6 mg	At end of surgery
Haloperidol	0.5–2 mg (IM or IV)	*c*	Not specified
Ondansetron	4 mg IV	50–100 mcg/kg up to 4 mg	At end of surgery
Palonosetron[b]	0.075 mg IV	Not labeled for patients < 18 y	At induction
Prochlorperazine	5–10 mg IM or IV	*c*	At end of surgery
Promethazine[d]	6.25–25 mg IV	*c*	At induction
Scopolamine	Transdermal patch	*c*	Prior evening or 4 h before surgery
Tropisetron	2 mg IV	0.1 mg/kg up to 2 mg	At end of surgery

[a]Based on recommendations from consensus guidelines; may differ from manufacturer's recommendations.
[b]Labeled for use in PONV but not included in consensus guidelines.
[c]Pediatric dosing not included in consensus guidelines.
[d]See Food and Drug Administration (FDA) "black box" warning.
From Gan et al.[50]

Treatment of PONV

Patients who experience PONV after receiving prophylactic treatment with a 5-HT_3-RA plus dexamethasone should receive rescue therapy from a different drug class such as a phenothiazine, metoclopramide, or droperidol.[50] Repeating the agent given for PONV prophylaxis within 6 hours of surgery is of no additional benefit.[60] Furthermore, a repeated dose of a 5-HT_3-RA is not effective in treatment of PONV.[61,62] An emetic episode occurring more than 6 hours postoperatively can be treated with any of the drugs used for prophylaxis except dexamethasone and transdermal scopolamine.[50]

If no prophylaxis was given, the recommended treatment is low-dose 5-HT_3-RA as follows: dolasetron 12.5 mg, granisetron 0.1 mg, ondansetron 1 mg, and tropisetron 0.5 mg. Alternative treatments for established PONV include dexamethasone 2 to 4 mg IV, droperidol 0.625 mg IV, or promethazine 6.25 to 12.5 mg IV.[63]

RADIATION-INDUCED NAUSEA AND VOMITING (RINV)

Nausea and vomiting associated with radiation therapy is not well understood. It is neither as predictable nor as severe as CINV, and many patients receiving radiation therapy will not experience nausea or vomiting. Risk factors associated with the development of RINV include the site of radiation, the dose, dose rate, and area of the body to be irradiated.

8 Patients receiving single-exposure, high-dose radiation therapy to the upper abdomen, or total or hemibody irradiation, should receive prophylactic antiemetics for RINV.

Prophylaxis of RINV

Four radiotherapy-induced emesis risk groups have been defined by the Antiemetic Subcommittee of the MASCC and the ASCO antiemetic practice guidelines.[2,33] Both groups recommend preventive therapy with a 5-HT_3-RA and dexamethasone in patients who are receiving total body irradiation (high emetic risk). The efficacy of oral granisetron 2 mg and ondansetron 8 mg was demonstrated in 34 patients who underwent hyperfractionated total body irradiation.[64] Patients undergoing radiation therapy procedures with moderate to low emetic risk should receive a 5-HT_3-RA prior to each fraction.

DISORDERS OF BALANCE

Disorders of balance include vertigo, dizziness, and motion sickness. The etiology of these complaints may include diseases that are infectious, postinfectious, demyelinative, vascular, neoplastic, degenerative, traumatic, toxic, psychogenic, or idiopathic. Symptoms of imbalance perceived by the patient present a particular clinical challenge. Whether associated with a minor or complex disorder, motion sickness may be associated with nausea and vomiting.

Beneficial therapy for patients in this setting can most reliably be found among the antihistaminic–anticholinergic agents. However, the precise mechanisms of action of these agents are currently unknown. Neither the antihistaminic nor the anticholinergic potency appears to correlate well with the ability of these agents to prevent or treat the nausea and vomiting associated with motion sickness. When used for their depressant effects on labyrinth excitability, these agents produce variable efficacy and safety profiles. Oral regimens of antihistaminic–anticholinergic agents given one to several times each day may be effective, especially when the first dose is administered prior to motion.

Scopolamine is commonly used to prevent nausea or vomiting caused by motion. The usefulness of scopolamine in preventing motion sickness was enhanced with the development of the transdermal system (patch) that increased patient satisfaction and decreased untoward side effects. A review of 12 randomized, controlled studies showed that scopolamine provided better protection from motion-induced sickness than did placebo, but was not superior to antihistamines and combinations of scopolamine and ephedrine.[65]

ANTIEMETIC USE DURING PREGNANCY

As many as 75% of pregnant women experience nausea and vomiting to some degree during the first trimester of pregnancy. The severity of the symptoms varies considerably, from mild nausea to incapacitating nausea and vomiting. Severity may be decreased by taking a multiple vitamin at the time of conception. The etiology of nausea and vomiting of pregnancy (NVP) is not well understood. For the majority of women, these symptoms are self-limited, although approximately 1% to 3% develop hyperemesis gravidarum, a serious condition marked by severe physical symptoms and/or medical complications requiring hospitalization. In its most

severe state, hyperemesis gravidarum may result in volume contraction, starvation, and electrolyte abnormalities.

Initial management of NVP often involves dietary changes and/or lifestyle modifications. Nonpharmacologic interventions for NVP include ginger[66] and acupressure, although efficacy trials for acupressure are lacking. Persistent nausea and/or vomiting leads to the consideration of drug therapy at a time when teratogenic potential of each agent must be considered.

Treatment recommendations for the management of NVP are available from the American College of Obstetricians and Gynecologists (ACOG).[67] A comprehensive review of treatment options for NVP was published.[68] Pyridoxine (10–25 mg 1–4 times daily), with or without doxylamine (12.5–20 mg 1–4 times daily), is recommended as first-line therapy. In cases of refractory NVP, addition of a histamine$_1$-receptor antagonist such as dimenhydrinate (50–100 mg orally or rectally every 4–6 hours as needed), diphenhydramine (25–50 mg orally or 10–50 mg IV every 4–6 hours as needed), or meclizine (25 mg orally every 4–6 hours as needed) is recommended. Dopamine antagonists can also be added if symptoms continue (metoclopramide 5–10 mg IV every 8 hours as needed; promethazine 12.5–25 mg IV every 4 hours as needed; prochlorperazine 5–10 mg orally every 6 hours as needed).

Patients with persistent NVP or who show signs of dehydration should receive intravenous fluid replacement with thiamine. Ondansetron 2 to 8 mg orally/IV every 8 hours as needed may alleviate NVP, but intravenous ondansetron was no more effective than promethazine for treatment of severe NVP.[69] Corticosteroids should be reserved for patients with refractory NVP or hyperemesis gravidarum; methylprednisolone 16 mg orally/IV every 8 hours for 3 days followed by a 2-week taper is recommended. This regimen may be repeated if necessary, but treatment should not exceed a total of 6 weeks.

ANTIEMETIC USE IN CHILDREN

CINV

Practice guidelines recommend that a corticosteroid (such as dexamethasone) plus a 5-HT$_3$-RA be administered to children receiving chemotherapy of high or moderate emetic risk.[33] Although studies show there is a wide variation in metabolism and clearance of 5-HT$_3$-RAs, higher weight-based doses have not been adequately studied in pediatric patients.[70]

Consensus guidelines suggest that there are no differences between 5-HT$_3$-RAs in safety or efficacy. However, a randomized, comparative study demonstrated that one dose of palonosetron 0.25 mg IV provided better complete control than ondansetron (8 mg/m^2 IV) in children treated with moderate to highly emetogenic chemotherapy.[71] This study needs to be confirmed in a larger randomized trial.

Gastroenteritis

For nausea and vomiting associated with pediatric gastroenteritis, emphasis should be placed on oral rehydration therapy (ORT); several products are commercially available. However, a recent meta-analyses has shown that pharmacotherapy may be a useful adjunct to ORT.[72] One double-blind study suggested that a single dose of ondansetron may facilitate ORT and reduced the need for IV fluids in children with gastroenteritis who were unable to tolerate oral intake.[73,74] While promethazine given in suppository form was the most often prescribed antiemetic for pediatric gastroenteritis, the Food and Drug Administration added a black box warning due to serious adverse events reports in children and adolescents, including death.[75,76]

PHARMACOECONOMIC CONSIDERATIONS

Cost of antiemetic drugs for the treatment of nausea and vomiting is only one variable to consider in a pharmacoeconomic outcome assessment. Other variables include the cost of managing complications and the impact on loss of work, functionality, and productivity as well as delays of potentially curable therapies. Inadequately controlled emesis can lead to unexpected hospitalizations for potentially serious complications including electrolyte deficiencies, dehydration, esophageal tears, and wound dehiscence.

It is economically and clinically important to develop antiemetic protocols based on appropriate decision analysis to optimize clinical outcomes. The clinical practice guidelines that have been previously described are valuable tools when developing institution-specific antiemetic protocols. The need to control antiemetic costs for health systems is universal and formulary management strategies have been described.[77]

CINV

A large study based on claims data was used to determined the costs associated with CINV over one cycle of chemotherapy.[78] Direct medical cost in the uncontrolled CINV group was estimated to be $1,300 (in 2006 U.S. dollars), or 30% higher than in the controlled CINV group. A sensitivity analysis demonstrated that a new antiemetic agent that could decrease the uncontrolled CINV rate from 50% to 10% would be cost-effective as long as the new drug cost is $500 or less.

PONV

As was presented earlier, the risk of developing PONV increases as the number of risk factors increase. Any occurrence of PONV would likely delay patient discharge from the post-anesthesia unit with a potential increase in the cost of patient care. Prophylactic antiemetic therapy was cost effective with a number needed to treat (NNT) of 3 to 4 (an NNT <5 is considered cost-effective).[79] In low-risk patients, the NNT was about 20 and not cost-effective.

EVALUATION OF EMETIC OUTCOMES

In assessing emetic outcomes, standardized monitoring criteria should include the subjective assessment of the patient's severity of nausea, as well as objective parameters, such as changes in patient weight, the number of vomiting episodes each day, the volume of vomitus lost, and evaluation of fluid, acid–base balance, and electrolyte status, with particular attention to serum sodium, potassium, and chloride concentrations. In addition, evaluation of renal function may become important, particularly in patients with volume contraction and progressive electrolyte disturbances. Specific parameters include daily urine volume, urine specific gravity, and urine electrolyte concentrations. Physical assessment of patients should include evaluation of mucous membranes and skin turgor, because dryness of these tissues may be indicative of significant volume loss.

For patients on chemotherapy, evaluation of emetic outcomes should occur after the administration of each chemotherapy cycle. Adherence to outpatient antiemetic regimens occurs in about 65% of patients. Delayed nausea and vomiting occurs in 15% to 40% of patients, depending on the emetic risk of the chemotherapy and the antiemetic regimen used for prophylaxis. Patients receiving high risk regimens are most likely to report symptoms of nausea and vomiting on day 3 after chemotherapy.[80] Symptom management assessments should be performed on the third or fourth day after chemotherapy. Documentation of a nausea and/or vomiting event will assist the clinician in modifying the antiemetic regimen for the next cycle of chemotherapy.

In the postsurgical anesthesia setting, assessment of nausea and vomiting is important for detecting dehydration, decreased blood pressure, or cardiac arrhythmias. Other complications of PONV include suture line tension, wound dehiscence, and increased bleeding under surgical flaps.[81]

CHAPTER 43

Diarrhea, Constipation, and Irritable Bowel Syndrome

PATRICIA H. POWELL AND VIRGINIA H. FLEMING

KEY CONCEPTS

1. Diarrhea is caused by many viral and bacterial organisms. It is most often a minor discomfort, not life threatening, and usually self-limited.
2. The four pathophysiologic mechanisms of diarrhea have been linked to the four broad diarrheal groups, which are secretory, osmotic, exudative, and altered intestinal transit. The three mechanisms by which absorption occurs from the intestines are active transport, diffusion, and solvent drag.
3. Management of diarrhea focuses on preventing excessive water and electrolyte losses, dietary care, relieving symptoms, treating curable causes, and treating secondary disorders.
4. Bismuth subsalicylate is marketed for indigestion, relieving abdominal cramps, and controlling diarrhea, including traveler's diarrhea, but may cause interactions with several components if given in excess.
5. Underlying causes of constipation should be identified when possible and corrective measures taken (e.g., alteration of diet or treatment of diseases such as hypothyroidism).
6. The foundation of treatment of constipation is dietary fiber or bulk-forming laxatives that provide 10–15 g/day of raw fiber.
7. Irritable bowel syndrome (IBS) is one of the most common gastrointestinal disorders characterized by lower abdominal pain, disturbed defecation, and bloating. Many nongastrointestinal manifestations also exist with IBS. Visceral hypersensitivity is a major culprit in the pathophysiology of the disease.
8. Dietary-predominant IBS should be managed by dietary modification and drugs such as loperamide when diet changes alone are insufficient to promote control of symptoms.
9. Several drug classes are useful in the treatment of the pain associated with IBS including tricyclic compounds and the gut-selective calcium channel blockers.

DIARRHEA

Diarrhea is a troublesome discomfort that affects most individuals in the United States at some point in their lives and can be thought of as both a symptom and a sign. Usually diarrheal episodes begin abruptly and subside within 1 or 2 days without treatment. This chapter focuses primarily on noninfectious diarrhea, with only minor reference to infectious diarrhea (see Chap. 122 for a discussion of gastrointestinal infections). Diarrhea is often a symptom of a systemic disease, and not all possible causes of diarrhea are discussed in this chapter. Acute diarrhea is commonly defined as <14 days' duration, persistent diarrhea as more than 14 days' duration, and chronic diarrhea as more than 30 days' duration.

To understand diarrhea, one must have a reasonable definition of the condition; unfortunately, the literature is extremely variable on this. Simply put, diarrhea is an increased frequency and decreased consistency of fecal discharge as compared to an individual's normal bowel pattern. Frequency and consistency are variable within and between individuals. For example, some individuals defecate as often as three times per day, whereas others defecate only two or three times per week. A Western diet usually produces a daily stool weighing between 100 and 300 g, depending on the amount of nonabsorbable materials (mainly carbohydrates) consumed. Patients with serious diarrhea may have a daily stool weight in excess of 300 g; however, a subset of patients experience frequent small, watery passages. Additionally, vegetable fiber-rich diets, such as those consumed in some Eastern cultures (e.g., those in Africa), produce stools weighing more than 300 g/day.

Diarrhea may be associated with a specific disease of the intestines or secondary to a disease outside the intestines. For instance, bacillary dysentery directly affects the gut, whereas diabetes mellitus causes neuropathic diarrheal episodes. Furthermore, diarrhea can be considered as acute or chronic disease. Infectious diarrhea is often acute; diabetic diarrhea is chronic. Congenital disorders in gastrointestinal ion-transport mechanisms are another cause of chronic diarrhea.[1] Whether acute or chronic, diarrhea has the same pathophysiologic causes that help in identification of specific treatments.

EPIDEMIOLOGY

The epidemiology of diarrhea varies in developed versus developing countries.[2] In the United States, diarrheal illnesses are usually not reported to the Centers for Disease Control and Prevention (CDC) unless associated with an outbreak or an unusual organism or condition. For example, the acquired immunodeficiency syndrome (AIDS) has been identified with protracted diarrheal illness. Diarrhea is a major problem in daycare centers and nursing homes, probably because early childhood and senescence plus environmental conditions are risk factors. Although an exact

epidemiologic profile in the United States is not available through the CDC or published literature, chronic diarrhea affects approximately 5% of the adult population and ranges from 3% to 20% in children worldwide.[3–5] In developing countries, diarrhea is a leading cause of illness and death in children, creating a tremendous economic strain on healthcare costs.

1 Most cases of acute diarrhea are caused by infections with viruses, bacteria, or protozoa and are generally self-limited.[6] Although viruses are more commonly associated with acute gastroenteritis, bacteria are responsible for more cases of acute diarrhea.

Evaluation of a noninfectious cause is considered if diarrhea persists and no infectious organism can be identified, or if the patient falls into a high-risk category for metabolic complications with persistent diarrhea. Common causative bacterial organisms include *Shigella, Salmonella, Campylobacter, Staphylococcus,* and *Escherichia coli*. Foodborne bacterial infection is a major concern, as several major food poisoning episodes have occurred that were traced to poor sanitary conditions in meat-processing plants. Acute viral infections are attributed mostly to the Norwalk and rotavirus groups.

PHYSIOLOGY

In the fasting state, 9 L of fluid enters the proximal small intestine each day. Of this fluid, 2 L are ingested through diet, while the remainder consists of internal secretions. Because of meal content, duodenal chyme is usually hypertonic. When chyme reaches the ileum, the osmolality adjusts to that of plasma, with most dietary fat, carbohydrate, and protein being absorbed. The volume of ileal chyme decreases to about 1 L/day upon entering the colon, which is further reduced by colonic absorption to 100 mL daily. If the small intestine water absorption capacity is exceeded, chyme overloads the colon, resulting in diarrhea. In humans, the colon absorptive capacity is about 5 L daily. Colonic fluid transport is critical to water and electrolyte balance.

Absorption from the intestines back into the blood occurs by three mechanisms: active transport, diffusion, and solvent drag. Active transport and diffusion are the mechanisms of sodium transport. Because of the high luminal sodium concentration (142 mEq/L), sodium diffuses from the sodium-rich gut into epithelial cells, where it is actively pumped into the blood and exchanged with chloride to maintain an isoelectric condition across the epithelial membrane.

Hydrogen ions are transported by an indirect mechanism in the upper small intestine. As sodium is absorbed, hydrogen ions are secreted into the gut. Hydrogen ions then combine with bicarbonate ions to form carbonic acid, which then dissociates into carbon dioxide and water. Carbon dioxide readily diffuses into the blood for expiration through the lung. The water remains in the chyme.

Paracellular pathways are major routes of ion movement. As ions, monosaccharides, and amino acids are actively transported, an osmotic pressure is created, drawing water and electrolytes across the intestinal wall. This pathway accounts for significant amounts of ion transport, especially sodium. Sodium plays an important role in stimulating glucose absorption. Glucose and amino acids are actively transported into the blood via a sodium-dependent cotransport mechanism. Cotransport absorption mechanisms of glucose-sodium and amino acid-sodium are extremely important for treating diarrhea.

Gut motility influences absorption and secretion. The amount of time in which luminal content is in contact with the epithelium is under neural and hormonal control. Neurohormonal substances, such as angiotensin, vasopressin, glucocorticoid, aldosterone, and neurotransmitters also regulate ion transport.

PATHOPHYSIOLOGY

2 Four general pathophysiologic mechanisms disrupt water and electrolyte balance, leading to diarrhea, and are the basis of diagnosis and therapy. These are (a) a change in active ion transport by either decreased sodium absorption or increased chloride secretion; (b) change in intestinal motility; (c) increase in luminal osmolarity; and (d) increase in tissue hydrostatic pressure. These mechanisms have been related to four broad clinical diarrheal groups: secretory, osmotic, exudative, and altered intestinal transit.

Secretory diarrhea occurs when a stimulating substance either increases secretion or decreases absorption of large amounts of water and electrolytes. Substances that cause excess secretion include vasoactive intestinal peptide (VIP) from a pancreatic tumor, unabsorbed dietary fat in steatorrhea, laxatives, hormones (such as secretion), bacterial toxins, and excessive bile salts. Many of these agents stimulate intracellular cyclic adenosine monophosphate and inhibit Na^+/K^+-adenosine triphosphatase (ATPase), leading to increased secretion. Also, many of these mediators inhibit ion absorption simultaneously. Secretory diarrhea is recognized by large stool volumes (>1 L/day) with normal ionic contents and osmolality approximately equal to plasma. Fasting does not alter the stool volume in these patients.

Poorly absorbed substances retain intestinal fluids, resulting in osmotic diarrhea. This process occurs with malabsorption syndromes, lactose intolerance, administration of divalent ions (e.g., magnesium-containing antacids), or consumption of poorly soluble carbohydrate (e.g., lactulose). As a poorly soluble solute is transported, the gut adjusts the osmolality to that of plasma; in so doing, water and electrolytes flux into the lumen. Clinically, osmotic diarrhea is distinguishable from other types, as it ceases if the patient resorts to a fasting state.

Inflammatory diseases of the gastrointestinal tract discharge mucus, serum proteins, and blood into the gut. Sometimes bowel movements consist only of mucus, exudate, and blood. Exudative diarrhea affects other absorptive, secretory, or motility functions to account for the large stool volume associated with this disorder.

Altered intestinal motility produces diarrhea by three mechanisms: reduction of contact time in the small intestine, premature emptying of the colon, and bacterial overgrowth. Chyme must be exposed to intestinal epithelium for a sufficient time period to enable normal absorption and secretion processes to occur. If this contact time decreases, diarrhea results. Intestinal resection or bypass surgery and drugs (such as metoclopramide) cause this type of diarrhea. On the other hand, an increased time of exposure allows fecal bacteria overgrowth. A characteristic small intestine diarrheal pattern is rapid, small, coupling bursts of waves. These waves are inefficient, do not allow absorption, and rapidly dump chyme into the colon. Once in the colon, chyme exceeds the colonic capability to absorb water.

Etiologic Examination of the Stool

Stool characteristics are important in assessing the etiology of diarrhea. A description of the frequency, volume, consistency, and color provides diagnostic clues. For instance, diarrhea starting in the small intestine produces a copious, watery or fatty (greasy), and foul-smelling stool; contains undigested food particles; and is usually free from gross blood. Colonic diarrhea appears as small, pasty, and sometimes bloody or mucoid movements. Rectal tenesmus with flatus accompanies large intestinal diarrhea.

CLINICAL PRESENTATION

Table 43–1 outlines the clinical presentation of diarrhea and Table 43–2 shows common drug-induced causes of diarrhea.

TABLE 43-1 Clinical Presentation of Diarrhea

General
- Usually, acute diarrheal episodes subside within 72 hours of onset, whereas chronic diarrhea involves frequent attacks over extended time periods.

Signs and symptoms
- Abrupt onset of nausea, vomiting, abdominal pain, headache, fever, chills, and malaise.
- Bowel movements are frequent and never bloody, and diarrhea lasts 12 to 60 hours.
- Intermittent periumbilical or lower right quadrant pain with cramps and audible bowel sounds is characteristic of small intestinal disease.
- When pain is present in large-intestinal diarrhea, it is a gripping, aching sensation with tenesmus (straining, ineffective, and painful stooling). Pain localizes to the hypogastric region, right or left lower quadrant, or sacral region.
- In chronic diarrhea, a history of previous bouts, weight loss, anorexia, and chronic weakness are important findings.

Physical examination
- Typically demonstrates hyperperistalsis with borborygmi and generalized or local tenderness.

Laboratory tests
- Stool analysis studies include examination for microorganisms, blood, mucus, fat, osmolality, pH, electrolyte and mineral concentration, and cultures.
- Stool test kits are useful for detecting gastrointestinal viruses, particularly rotavirus.
- Antibody serologic testing shows rising titers over a 3- to 6-day period, but this test is not practical and is nonspecific.
- Occasionally, total daily stool volume is also determined.
- Direct endoscopic visualization and biopsy of the colon may be undertaken to assess for the presence of conditions such as colitis or cancer.
- Radiographic studies are helpful in neoplastic and inflammatory conditions.

TABLE 43-2 Drugs Causing Diarrhea

Laxatives
Antacids containing magnesium
Antineoplastics
Auranofin (gold salt)
Antibiotics
- Clindamycin
- Tetracyclines
- Sulfonamides
- Any broad-spectrum antibiotic

Antihypertensives
- Reserpine
- Guanethidine
- Methyldopa
- Guanabenz
- Guanadrel
- Angiotensin-converting enzyme inhibitors

Cholinergics
- Bethanechol
- Neostigmine

Cardiac agents
- Quinidine
- Digitalis
- Digoxin

Nonsteroidal antiinflammatory drugs
Misoprostol
Colchicine
Proton pump inhibitors
H_2-receptor blockers

A medication history is extremely important in identifying drug-induced diarrhea. Many agents, including antibiotics and other drugs, cause diarrhea or, less commonly, pseudomembranous colitis. Self-inflicted laxative abuse for weight loss is popular.

Most acute diarrhea is self-limiting, subsiding within 72 hours. However, infants, young children, the elderly, and debilitated persons are at risk for morbid and mortal events in prolonged or voluminous diarrhea. These groups are at risk for water, electrolyte, and acid-base disturbances, and potentially cardiovascular collapse and death. The prognosis for chronic diarrhea depends on the cause; for example, diarrhea secondary to diabetes mellitus waxes and wanes throughout life.

TREATMENT

Diarrhea

PREVENTION

Acute viral diarrheal illness often occurs in daycare centers and nursing homes. Because person-to-person contact is the mechanism by which viral disease spreads, isolation techniques must be initiated. For bacterial, parasitic, and protozoal infections, strict food handling, sanitation, water, and other environmental hygiene practices can prevent transmission. If diarrhea is secondary to another illness, controlling the primary condition is necessary. Antibiotics and bismuth subsalicylate are advocated to prevent traveler's diarrhea, in conjunction with treatment of drinking water and caution with consumption of fresh vegetables.[7]

DESIRED OUTCOME

3 If prevention is unsuccessful and diarrhea occurs, therapeutic goals are to (a) manage the diet; (b) prevent excessive water, electrolyte, and acid-base disturbances; (c) provide symptomatic relief; (d) treat curable causes; and (e) manage secondary disorders causing diarrhea (Figs. 43–1 and 43–2).

Clinicians must clearly understand that diarrhea, like a cough, may be a body defense mechanism for ridding itself of harmful substances or pathogens. The correct therapeutic response is not necessarily to stop diarrhea at all costs.

NONPHARMACOLOGIC MANAGEMENT

Dietary management is a first priority in the treatment of diarrhea. Most clinicians recommend discontinuing consumption of solid foods and dairy products for 24 hours. However, fasting is of questionable value, as this treatment modality has not been extensively studied. In osmotic diarrhea, these maneuvers control the problem. If the mechanism is secretory, diarrhea persists. For patients who are experiencing nausea and/or vomiting, a mild, digestible, low-residue diet should be administered for 24 hours. If vomiting is present and uncontrollable with antiemetics (see Chap. 42), nothing is taken by mouth. As bowel movements decrease, a bland diet is begun.

Feeding should continue in children with acute bacterial diarrhea. Fed children have less morbidity and mortality, whether or not they receive oral rehydration fluids. Studies are not available in the elderly or in other high-risk groups to determine the value of continued feeding in bacterial diarrhea.

Water and Electrolytes

Rehydration and maintenance of water and electrolytes are primary treatment goals until the diarrheal episode ends. If the patient is volume depleted, rehydration should be directed at replacing water

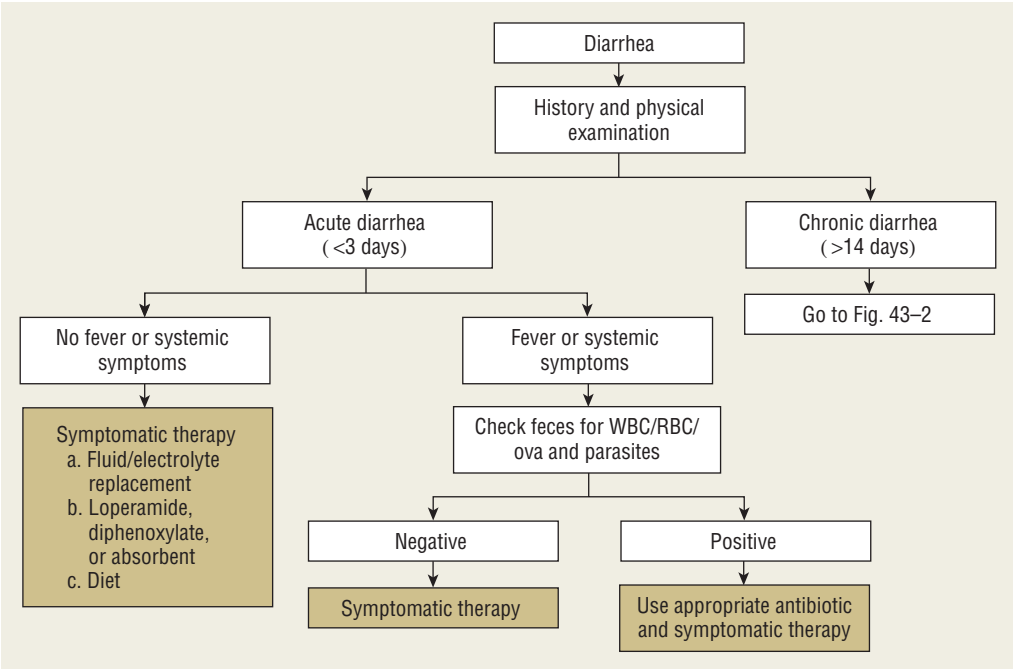

FIGURE 43-1. Recommendations for treating acute diarrhea. Follow these steps: (a) Perform a complete history and physical examination. (b) Is the diarrhea acute or chronic? If chronic diarrhea, go to Figure 43–2. (c) If acute diarrhea, check for fever and/or systemic signs and symptoms (i.e., toxic patient). If systemic illness (fever, anorexia, or volume depletion), check for an infectious source. If positive for infectious diarrhea, use appropriate antibiotic/anthelmintic drug and symptomatic therapy. If negative for infectious cause, use only symptomatic treatment. (d) If no systemic findings, then use symptomatic therapy based on severity of volume depletion, oral or parenteral fluid/electrolytes, antidiarrheal agents (see Table 43–4), and diet. (RBC, red blood cells; WBC, white blood cells.)

and electrolytes to normal body composition. Then water and electrolyte composition are maintained by replacing losses. Many patients will not develop volume depletion and therefore will only require maintenance fluid and electrolyte therapy. Parenteral and enteral routes may be used for supplying water and electrolytes. If vomiting and dehydration are not severe, enteral feeding is the less costly and preferred method. In the United States, many commercial oral rehydration preparations are available (Table 43–3).

Because of concerns about hypernatremia, physicians continue to hospitalize patients and use intravenous fluids to correct fluid and electrolyte deficits in severe dehydration. Oral solutions are strongly recommended.[8–10] In developing countries, the World Health Organization Oral Rehydration Solution (WHO-ORS) saves the lives of millions of children annually.

During diarrhea, the small intestine retains its ability to actively transport monosaccharides such as glucose. Glucose actively carries sodium with water and other electrolytes. The WHO now recommends an ORS with a lower osmolarity, sodium content, and glucose load (see Table 43–3).[11] A separate oral supplement of zinc 20 mg daily for 14 days in addition to ORS significantly reduces the severity and duration of acute diarrhea in developing countries.[8,12] ORS is a lifesaving treatment for millions afflicted in developing countries. Acceptance in developed countries is less enthusiastic; however, the advantage of this product in reducing hospitalizations may prove its use as a cost-effective alternative, saving millions of dollars in healthcare expenditures.

PHARMACOLOGIC THERAPY

Various drugs have been used to treat diarrheal attacks (Table 43–4), including antimotility agents, adsorbents, antisecretory compounds, antibiotics, enzymes, and intestinal microflora. Usually these drugs are not curative but palliative.

Opiates and Their Derivatives

Opiates and opioid derivatives (a) delay the transit of intraluminal contents or (b) increase gut capacity, prolonging contact and absorption. Enkephalins, which are endogenous opioid substances, regulate fluid movement across the mucosa by stimulating absorptive processes. Limitations to the use of opiates include an addiction potential (a real concern with long-term use) and worsening of diarrhea in selected infectious diarrhea.

Most opiates act through peripheral and central mechanisms with the exception of loperamide, which acts only peripherally. Loperamide is antisecretory; it inhibits the calcium-binding protein calmodulin, controlling chloride secretion. Loperamide, available as 2 mg capsules or 1 mg/5 mL solution (both are nonprescription products), is suggested for managing acute and chronic diarrhea. The usual adult dose is initially 4 mg orally, followed by 2 mg after each loose stool, up to 16 mg/day. Used correctly, this agent has rare side effects, such as dizziness and constipation. If the diarrhea is concurrent with a high fever or bloody stool, the patient should be referred to a physician. Also, diarrhea lasting 48 hours beyond initiating loperamide warrants medical attention. Loperamide can also be used in traveler's diarrhea. It is comparable to bismuth subsalicylate for treatment of this disorder.[7]

Diphenoxylate is available as a 2.5 mg tablet and as a 2.5 mg/5 mL solution. A small amount of atropine (0.025 mg) is included in the product to discourage abuse. In adults, when taken as 2.5 to 5 mg three or four times daily, not to exceed a 20 mg total daily dose, diphenoxylate is rarely toxic. Some patients may complain of atropinism (blurred vision, dry mouth, and urinary hesitancy). Like loperamide, it should not be used in patients who are at risk of bacterial enteritis with *E. coli, Shigella,* or *Salmonella*.

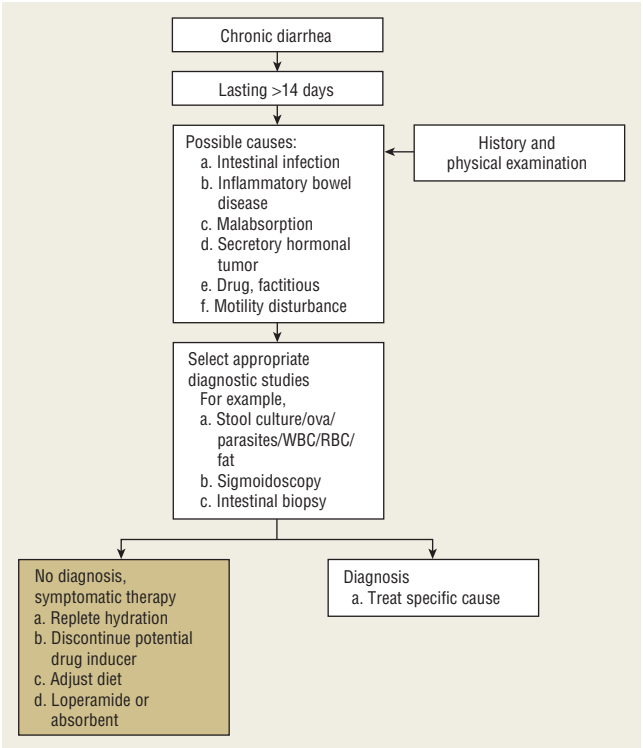

FIGURE 43-2. Recommendations for treating chronic diarrhea. Follow these steps: (a) Perform a careful history and physical examination. (b) The possible causes of chronic diarrhea are many. These can be classified into intestinal infections (bacterial or protozoal), inflammatory disease (Crohn disease or ulcerative colitis), malabsorption (lactose intolerance), secretory hormonal tumor (intestinal carcinoid tumor or vasoactive intestinal peptide-secreting tumor [VIPoma]), drug (antacid), factitious (laxative abuse), or motility disturbance (diabetes mellitus, irritable bowel syndrome, or hyperthyroidism). (c) If the diagnosis is uncertain, selected appropriate diagnostic studies should be ordered. (d) Once diagnosed, treatment is planned for the underlying cause with symptomatic antidiarrheal therapy. (e) If no specific cause can be identified, symptomatic therapy is prescribed. (RBC, red blood cells; WBC, white blood cells.)

Difenoxin, a diphenoxylate derivative also chemically related to meperidine, is also combined with atropine and has the same uses, precautions, and side effects. Marketed as a 1 mg tablet, the adult dosage is 2 mg initially, followed by 1 mg after each loose stool, not to exceed 8 mg/day.

Paregoric, camphorated tincture of opium, is marketed as a 2 mg/5 mL solution and is indicated for managing both acute and chronic diarrhea. It is not widely prescribed today because of its abuse potential.

CLINICAL CONTROVERSY

Long-term use of oral opiates is not routinely recommended for several pharmacologic reasons. Some opioids such as morphine and codeine have the tendency to cause constipation by slowing down the peristaltic action of the bowels, which can also result in a functional ileus. This effect can be minimized by administering laxatives and/or stool softeners in patients who require long-term opiate therapy. Prokinetic agents may also be helpful in treating opiate-related constipation.

Adsorbents

Adsorbents are used for symptomatic relief. These products, many not requiring a prescription, are nontoxic, but their effectiveness remains unproven. Adsorbents are nonspecific in their action; they adsorb nutrients, toxins, drugs, and digestive juices. Polycarbophil absorbs 60 times its weight in water and can be used to treat both diarrhea and constipation. It is a nonprescription product and is sold as a 500 mg chewable tablet. This hydrophilic, nonabsorbable product is safe and may be taken four times daily, up to 6 g/day in adults. See Table 43–4 for selected antidiarrheal preparations.

Antisecretory Agents

Bismuth subsalicylate appears to have antisecretory, antiinflammatory, and antibacterial effects. As a nonprescription product, it is marketed for indigestion, relieving abdominal cramps, and controlling diarrhea, including traveler's diarrhea. Bismuth subsalicylate dosage strengths are a 262 mg chewable tablet, 262 mg/5 mL liquid, and 524 mg/15 mL liquid. The usual adult dose is 2 tablets or 30 mL every 30 minutes to 1 hour up to 8 doses per day.

4 Bismuth subsalicylate contains multiple components that might be toxic if given excessively to prevent or treat diarrhea. For instance, an active ingredient is salicylate, which may interact with anticoagulants or may produce salicylism (tinnitus, nausea, and vomiting). Bismuth reduces tetracycline absorption and may interfere with select gastrointestinal radiographic studies. Patients may complain of a darkening of the tongue and stools with repeat

TABLE 43-3 Oral Rehydration Solutions

	WHO-ORS[a]	Pedialyte[b] (Ross)	Rehydralyte[b] (Ross)	Enfalyte (Mead Johnson)	Resol[b] (Wyeth)

TABLE 43-4 Selected Antidiarrheal Preparations

	Dose Form	Adult Dose
Antimotility		
Diphenoxylate	2.5 mg/tablet 2.5 mg/5 mL	5 mg four times daily; do not exceed 20 mg/day
Loperamide	2 mg/capsule 2 mg/capsule	Initially 4 mg, then 2 mg after each loose stool; do not exceed 16 mg/day
Paregoric	2 mg/5 mL (morphine)	5–10 mL one to four times daily
Opium tincture	10 mg/mL (morphine)	0.6 mL four times daily
Difenoxin	1 mg/tablet	2 tablets, then 1 tablet after each loose stool; up to 8 tablets/day
Adsorbents		
Kaolin-pectin mixture	5.7 g kaolin + 130.2 mg pectin/30 mL	30–120 mL after each loose stool
Polycarbophil	500 mg/tablet	Chew 2 tablets four times daily or after each loose stool; do not exceed 12 tablets/day
Attapulgite	750 mg/15 mL 300 mg/7.5 mL 750 mg/tablet 600 mg/tablet 300 mg/tablet	1200–1500 mg after each loose bowel movement or every 2 hours; up to 9000 mg/day
Antisecretory		
Bismuth subsalicylate	1050 mg/30 mL 262 mg/15 mL 524 mg/15 mL 262 mg/tablet	Two tablets or 30 mL every 30 min to 1 h as needed up to 8 doses/day
Enzymes (lactase)	1,250 neutral lactase units/4 drops 3,300 FCC lactase units per tablet	3–4 drops taken with milk or dairy product
Bacterial replacement (*Lactobacillus acidophilus, Lactobacillus bulgaricus*)		2 tablets or 1 granule packet three to four times daily; give with milk, juice, or water
Octreotide	0.05 mg/mL 0.1 mg/mL 0.5 mg/mL	Initial: 50 mcg subcutaneously One to two times per day and titrate dose based on indication up to 600 mcg/day in two to four divided doses

administration. Salicylate can induce gout attacks in susceptible individuals.

Bismuth subsalicylate suspension has been evaluated in the treatment of secretory diarrhea of infectious etiology as well. In a dose of 30 mL every 30 minutes for eight doses, unformed stools decrease in the first 24 hours. Bismuth subsalicylate may also be effective in preventing traveler's diarrhea.

Octreotide, a synthetic octapeptide analog of endogenous somatostatin, is effective for the symptomatic treatment of carcinoid tumors and other peptide-secreting tumors, dumping syndrome, and chemotherapy-induced diarrhea.[13] It has had limited success in patients with AIDS-associated diarrhea and short-bowel syndrome, does not appear to have an advantage over various opiate derivatives in the treatment of chronic idiopathic diarrhea, and has the disadvantage of being administered by injection.[14] Metastatic intestinal carcinoid tumors secrete excessive amounts of vasoactive substances, including histamine, bradykinin, serotonin, and prostaglandins. Primary carcinoid tumors occur throughout the gastrointestinal tract, with most in the ileum. Predominant signs and symptoms experienced by patients with these tumors are attributable to excessive concentrations of 5-hydroxytryptophan and serotonin. The totality of their clinical effects is termed the carcinoid syndrome. Some patients have a violent, watery diarrhea with abdominal cramping. Initially, diarrhea might be managed with various agents such as codeine, diphenoxylate, cyproheptadine, methysergide, phenoxybenzamine, or methyldopa. But octreotide is now considered first-line therapy for carcinoid syndrome.

Octreotide blocks the release of serotonin and many other active peptides and has been effective in controlling diarrhea and flushing. It is reported to have direct inhibitory effects on intestinal secretion and stimulatory effects on intestinal absorption. Non—gastrin-secreting adenomas of the pancreas are tumors associated with profuse watery diarrhea. This condition has been referred to as Verner-Morrison syndrome, WDHA (watery diarrhea, hypokalemia, and achlorhydria) syndrome, pancreatic cholera, watery diarrhea syndrome, and vasoactive intestinal peptide-secreting tumor (VIPoma). Excessive secretion of VIP from a retroperitoneal or pancreatic tumor produces most of the clinical features. Surgical tumor dissection is the treatment of choice. In nonsurgical candidates, the profuse watery diarrhea and other symptoms commonly encountered are managed with octreotide.

The dose of octreotide varies with the indication, disease severity, and patient response.[13] For managing diarrhea and flushing associated with carcinoid tumors in adults, the initial dosage range is 100 to 600 mcg/day in two to four divided doses subcutaneously for 2 weeks. For controlling secretory diarrhea of VIPomas, the dosage range is 200 to 300 mcg/day in two to four divided doses for 2 weeks. Some patients may require higher doses for symptomatic control. Patients responding to these initial doses may be switched to Sandostatin LAR Depot, a long-acting octreotide formulation. This product consists of microspheres containing the drug. Initial doses consist of 20 mg given intramuscularly intragluteally at 4-week intervals for 2 months. It is recommended that during the first 2 weeks of therapy the short-acting formulation also be administered subcutaneously. At the end of 2 months, patients with good symptom control may have the dose reduced to 10 mg every 4 weeks, while those without sufficient symptom control may have the dose increased to 30 mg every 4 weeks. For patients experiencing recurrence of symptoms on the 10 mg dose, dosage adjustment to 20 mg should be made. It is not uncommon for patients with carcinoid tumors or VIPomas to experience periodic exacerbation of symptoms. Subcutaneous octreotide for several days should be reinstituted in these individuals. In so-called carcinoid crisis, octreotide is given as an intravenous infusion at 50 mcg/h for 8 to 24 hours.

Because octreotide inhibits many other gastrointestinal hormones, it has a variety of intestinal side effects. With prolonged use,

gallbladder and biliary tract complications such as cholelithiasis have been reported. Approximately 5% to 10% of patients complain of nausea, diarrhea, and abdominal pain. Local injection pain occurs with about an 8% incidence. With high doses, octreotide may reduce dietary fat absorption, leading to steatorrhea.

Two other somatostatin analogs, lanreotide and vapreotide, have been studied.[14,15] Lanreotide is approved for use in the United States for acromegaly. The starting dose is 90 mg subcutaneously every 4 weeks for 3 months, then the dose is adjusted based upon growth hormone and insulin-like growth factor levels.[16] Vapreotide is an orphan drug that is indicated for pancreatic and gastrointestinal fistulas as well as esophageal variceal bleeding.

Miscellaneous Products

Probiotics are microorganisms that have been used for many years to replace colonic microflora. This supposedly restores normal intestinal function and suppresses the growth of pathogenic microorganisms. *Saccharomyces boulrdii*, *Lactobacillus GG,* and *Lactobacillus acidophilus* have been shown to decrease the duration of infectious and antibiotic-induced diarrhea in adults and children.[17] A combination probiotic product, VSL#3 (which contains multiple strains of lactobacilli and bifidobacteria) may have benefit in preventing radiation-induced diarrhea when given three times a day.[18] The dosage of probiotic preparations varies depending on the brand used. Intestinal flatus is the primary patient complaint experienced with this modality.

Anticholinergic drugs such as atropine block vagal tone and prolong gut transit time. Drugs with anticholinergic properties are present in many nonprescription products. Their value in controlling diarrhea is questionable and limited because of side effects. Angle-closure glaucoma, selected heart diseases, and obstructive uropathies are relative contraindications to the use of anticholinergic agents.

Lactase enzyme products are helpful for patients who are experiencing diarrhea secondary to lactose intolerance. Lactase is required for carbohydrate digestion. When a patient lacks this enzyme, eating dairy products causes an osmotic diarrhea. Several products are available for use each time a dairy product, especially milk or ice cream, is consumed.

Investigational Drugs

Several new classes of compounds are undergoing clinical trials for efficacy in acute diarrhea.[19] Enkephalins are endogenous opiate compounds in the gut that have antisecretory and proabsorptive activity in the small intestine. They promote sodium and chloride reabsorption via stimulation of a nonadrenergic, noncholinergic neurotransmitter. Enkephalinase inhibitors are compounds that slow down the enzymatic (i.e., enkephalinase) breakdown of endogenous enkephalins found in the small intestines. They exert an antisecretory effect without affecting GI motility or CNS-related effects/side effects. One specific compound, originally called acetorphan but now referred to as racecadotril, has been extensively tested in humans and found to be equal to other opiate antidiarrheals such as loperamide, while causing less GI motility side effects such as abdominal bloating, pain, and constipation.[20–22] Racecadotril is currently licensed only in France and a few developing countries with a high incidence of childhood diarrhea.

Vaccines are a new therapeutic frontier in controlling infectious diarrheas, especially in developing countries.[23–24] An oral vaccine for cholera is licensed and available in other countries (Dukoral from SBL Vaccines) and appears to provide somewhat better immunity and has fewer adverse effects than the previously available parenteral vaccine. However, the CDC does not recommend cholera vaccines for most travelers, nor is the vaccine available in the United States.

Oral *Shigella* vaccine, although effective under field conditions, requires 5 weekly oral doses and repeat booster doses, thereby limiting its practicality for use in developing nations. With about 1,500 serotypes for *Salmonella*, a vaccine is not currently available for humans. There are two newer typhoid vaccine formulations, one a parenteral inactivated whole-cell vaccine and the other an oral live-attenuated (Ty21a) vaccine that is administered in four doses on days 1, 3, 5, and 7, to be completed at least l week before exposure. Two rotavirus vaccines have been shown to prevent gastroenteritis due to rotavirus infection in infants and children.[25] The pentavalent human-bovine reassortant vaccine (RotaTeq from Merck) is administered as a three-oral-dose sequence, and the monovalent human vaccine (Rotarix from GlaxoSmithKline) is administered as a two-oral-dose sequence. A rotavirus vaccine program has been formed to reduce child morbidity and mortality from diarrheal disease by accelerating the availability of rotavirus vaccines appropriate for use in developing countries.

EVALUATION OF THERAPEUTIC OUTCOMES

General Outcomes Measures

Therapeutic outcomes are directed toward key symptoms, signs, and laboratory studies. Constitutional symptoms usually improve within 24 to 72 hours. Monitoring for changes in the frequency and character of bowel movements on a daily basis in conjunction with vital signs and improvement in appetite are of utmost importance. Also, the clinician needs to monitor body weight, serum osmolality, serum electrolytes, complete blood cell counts, urinalysis, and culture results (if appropriate).

Acute Diarrhea

Most patients with acute diarrhea experience mild to moderate distress. In the absence of moderate to severe dehydration, high fever, and blood or mucus in the stool, this illness is usually self-limiting within 3 to 7 days. Mild to moderate acute diarrhea is usually managed on an outpatient basis with oral rehydration, symptomatic treatment, and diet. Elderly persons with chronic illness as well as infants may require hospitalization for parenteral rehydration and close monitoring.

Severe Diarrhea

In the urgent/emergent situation, restoration of the patient's volume status is the most important outcome. Toxic patients (fever dehydration, hematochezia, or hypotension) require hospitalization, intravenous fluids and electrolyte administration, and empiric antibiotic therapy while awaiting culture and sensitivity results. With timely management, these patients usually recover within a few days.

CONSTIPATION

Constipation is a commonly encountered medical condition in the United States for which many patients initiate self-treatment. Constipation also accounts for many emergency room, primary care, gasteroenterologist, and pediatrician visits each year in the United States.[26] Though often considered more of a minor uncomfortable or unpleasant problem, constipation can have serious consequences and be costly to the healthcare system. One of the major underlying problems contributing to constipation in the Western world is lack of adequate dietary fiber. An additional contributing factor is public misconception about normal

bowel function. Many people believe that daily bowel movements are required for normal health or that accumulation of toxic substances will occur with infrequent defecation. Inappropriate laxative use by the general public may result from these misconceptions.

Constipation does not have a single, generally agreed upon definition. A general definition from the American Gastroenterology Association (AGA) defines functional constipation as a bowel disorder characterized by difficult, infrequent, or seemingly incomplete defecation that does not meet criteria for irritable bowel syndrome (IBS).[27] The lay public and healthcare professionals often define/describe constipation in a number of both quantitative and qualitative ways. Physicians often use stool frequency to define constipation (most commonly fewer than three bowel movements per week); however, the "normal" frequency of bowel movement is not well established (and can vary from person to person). Patients more often describe constipation in terms of symptoms or a combination of quantitative and qualitative descriptors that are difficult to quanitfy: bowel movement frequency, stool size or consistency (hard or lumpy stools), straining upon defecation, inability to defecate at will, and symptoms such as sensation of incomplete evacuation.

Examples of definitions of constipation that have been used in clinical studies include the following: (a) fewer than three stools per week for women and five stools per week for men despite a high-residue diet, or a period of more than 3 days without a bowel movement; (b) straining (incomplete evacuation, hard/lumpy stools, etc.) at stool greater than 25% of the time and/or two or fewer stools per week; or (c) straining at defecation and less than one stool daily with minimal effort. A symptom-based system for classifying functional constipation (and other functional gastrointestinal disorders) called the Rome criteria is often used to define constipation in clinical trials today. The Rome criteria encompass both quantitative (frequency) and qualitative (stool consistency, etc.) symptoms associated with constipation. The most current revision of the criteria, Rome III, was released in 2006 and is outlined in Table 43–5.

EPIDEMIOLOGY

A systematic review of the epidemiology of constipation in North America reported a prevalence range for constipation of 1.9% to 27%, with most reported estimates ranging from 12% to 19%.[28] Prevalence estimates by gender were female-to-male ratio of 2.2:1.[28] Similarly, in a multinational survey of 13,879 adult participants from seven countries, the rate of self-reported constipation was 12.3% overall (range 5% to 18%). Constipation was more common in women (2.4-fold more likely) and the elderly.[29] Other factors associated with constipation in some reports include inactivity, lower socioeconomic class, lower income, non-Caucasian race, symptoms of depression, and history of physical or sexual abuse.[28,30]

TABLE 43-5 Diagnostic Criteria for Functional Constipation[27,a]

1. Must include two or more of the following:
   a. Straining during at least 25% of defecations
   b. Lumpy or hard stools in at least 25% of defecations
   c. Sensation of incomplete evacuation for at least 25% of defecations
   d. Sensation of anorectal obstruction/blockage for at least 25% of defecations
   e. Manual maneuvers to facilitate at least 25% of defecations (e.g., digital evacuation, support of the pelvic floor)
   f. Fewer than three defecations per week
2. Loose stools are rarely present without the use of laxatives
3. There is insufficient evidence for IBS

[a]Criteria fulfilled for the last 3 months with symptoms onset at least 6 months prior to diagnosis

Although bowel movement frequency does not decrease as a consequence of aging, there is an age-related increase in laxative use and self-reported constipation rates.[28,31] Factors associated with the increased prevalence of constipation in the elderly include a higher number of daily medications, increased incidence of chronic comorbidities, changes in mobility status, changes in diet/lifestyle, and institutuionalization.

PATHOPHYSIOLOGY

Constipation may be primary or secondary. Primary constipation occurs without an identifiable underlying cause, whereas secondary constipation may be the result of constipating drugs, lifestyle factors, or medical disorders (Table 43–6). Three primary constipation subtypes exist–normal transit, slow transit, and disordered defecation (also referred to by various other names such as pelvic floor dysfunction, anorectal dyssynergia, outlet constipation, dyscoordinated pelvic muscle activity).[30] Normal transit constipation is the most common and often referred to as "functional constipation." These patients have normal GI motility and stool frequency but may experience difficulty evacuating, passage of hard stools, or bloating and abdominal discomfort. Slow transit constipation represents an abnormality of GI transit time that leads to infrequent defecation. Dysfunction of the pelvic floor muscles and/or

TABLE 43-6 Possible Causes of Constipation

Conditions	Possible Causes
GI disorders	Irritable bowel syndrome
	Diverticulitis
	Upper GI tract diseases
	Anal and rectal diseases
	Hemorrhoids
	Anal fissures
	Ulcerative proctitis
	Tumors
	Hernia
	Volvulus of the bowel
	Syphilis
	Tuberculosis
	Helminthic infections
	Lymphogranuloma venereum
	Hirschsprung's disease
Metabolic and endocrine disorders	Diabetes mellitus with neuropathy
	Hypothyroidism
	Panhypopituitarism
	Pheochromocytoma
	Hypercalcemia
	Enteric glucagon excess
Cardiac disorders	Heart failure
Pregnancy	Depressed gut motility
	Increased fluid absorption from colon
	Use of iron salts
Lifestyle factors	Dietary changes
	Inadequate fluid intake
	Low dietary fiber
	Decreased physical activity
Neurogenic causes	CNS diseases
	Trauma to the brain (particularly the medulla)
	Spinal cord injury
	CNS tumors
	Cerebrovascular accidents
	Parkinson disease
Psychogenic causes	Ignoring or postponing urge to defecate
	Psychiatric diseases
Drug induced	See Table 43–7

anal sphincter are the most frequently encountered reasons for disordered defecation. In patients with defecatory disorders, these muslces/sphinter (which normally relax during defecation) contract and impede evacuation of stool. It is common for the subtypes to overlap in a single patient.

5 Approaches to the treatment of constipation should begin with attempts to determine its cause. Disorders of the GI tract (IBS or diverticulitis), metabolic disorders (diabetes), or endocrine disorders (hypothyroidism) or other secondary causes may be involved. Constipation commonly results from a diet low in fiber or from use of constipating drugs such as opiates. Finally, constipation may sometimes be psychogenic in origin. Each of these causes is discussed in the following sections.

Constipation is a frequently reported problem in the elderly, probably the result of improper diets (low in fiber and liquids), increasing number of daily medications, diminished abdominal wall muscular strength, and possibly diminished physical activity. However, as previously stated, the frequency of bowel movements is not decreased with normal aging.

Drug-Induced Constipation

Use of drugs that inhibit the neurologic or muscular function of the GI tract, particularly the colon, may result in constipation. The majority of cases of drug-induced constipation are caused by opiates, various agents with anticholinergic properties, and antacids containing aluminum or calcium. With most of the agents listed in Table 43–7, the inhibitory effects on bowel function are dose dependent, with larger doses clearly causing constipation more frequently.

Opiates have effects on all segments of the bowel, but effects are most pronounced on the colon. The major mechanism by which opiates produce constipation has been proposed to be prolongation of intestinal transit time by causing spastic, nonpropulsive contractions. An additional contributory mechanism may be an increase in electrolyte absorption.

All opiate derivatives are associated with constipation, but the degree of intestinal inhibitory effects seems to differ between agents. Orally administered opiates appear to have greater inhibitory effects than parenterally administered products. Orally administered enkephalins (endogenous opiate-like polypeptides) have antimotility properties. In some reports, transdermal fentanyl has been associated with less constipation than oral sustained-release morphine.[32]

TABLE 43-7 Drugs Causing Constipation

- Analgesics
  - Inhibitors of prostaglandin synthesis
  - Opiates
- Anticholinergics
  - Antihistamines
  - Antiparkinsonian agents (e.g., benztropine or trihexyphenidyl)
  - Phenothiazines
  - Tricyclic antidepressants
- Antacids containing calcium carbonate or aluminum hydroxide
- Barium sulfate
- Calcium channel blockers
- Clonidine
- Diuretics (non-potassium-sparing)
- Ganglionic blockers
- Iron preparations
- Muscle blockers (D-tubocurarine, succinylcholine)
- Nonsteroidal antiinflammatory agents
- Polystyrene sodium sulfonate

TABLE 43-8 Clinical Evaluation of Constipation

History and physical examination

- Clarify what the patient means by constipation, identifying specific signs and symptoms (i.e., infrequent bowel movements, stools that are hard, small, or dry; difficulty or pain of defecation, feeling of abdominal discomfort or bloating, incomplete evacuation, etc.)
- Ask specifically about presence of Alarm signs and symptoms
- Evaluate general health, psychological status, medications, diet, comorbidities, onset of symptoms, and what treatments have been tried
- Identify underlying secondary causes or conditions (Table 43–6)
- Perform rectal exam for presence of anatomical abnormalities (such as fistulas, fissures, hemorrhoids, rectal prolapse) or abnormalities of perianal descent. Digital examination of rectum to check for fecal impaction, anal stricture, or rectal mass.

Laboratory tests

- No routine recommendations for lab testing–as indicated by clinical discretion
- In patients with signs and symptoms suggestive of organic disorder, specific testing may be performed (i.e., thyroid-function tests, electrolytes, glucose, complete blood count) based on clinical presentation
- In patients with alarm signs and symptoms or when structural disease is a possibility, select appropriate diagnostic studies:
  1. Protoscopy
  2. Sigmoidoscopy
  3. Colonoscopy
  4. Barium enema

CLINICAL PRESENTATION

See Table 43–8.

TREATMENT

Constipation

GENERAL APPROACH TO TREATMENT

Evaulation of constipation should attempt to clarify the patient's specific symptoms (i.e., exactly what the patient means by constipation). The patient should be asked about the frequency of bowel movements and the chronicity of constipation. Constipation occurring recently in an adult may indicate significant colon pathology such as malignancy. Constipation present since early infancy may be indicative of neurologic disorders. The patient should also be carefully questioned about usual diet and laxative regimens. Does the patient have a diet consistently deficient in high-fiber items and containing mainly highly refined foods? What laxatives or cathartics has the patient used to attempt relief of constipation? The patient should be questioned about other concurrent medications, with interest focused on agents that might cause constipation. Each patient should be questioned specifically to identify any "alarm symptoms" that would warrant further diagnostic workup[33] (Table 43–9). Evaulation should also include assessment of general health status, signs of underlying medical illness (i.e., hypothyroidism), and psychological status (e.g., depression or other psychological illness).

For most patients who complain of constipation, a thorough physical examination is not required after it is established that constipation (a) is not a chronic problem, (b) is not accompanied by signs of significant GI disease (i.e., alarm symptoms such as rectal bleeding or anemia), and (c) does not cause severe discomfort. In these circumstances, the patient may be referred directly to the first-line therapies for constipation described in the next section (mainly

TABLE 43-9 Alarm Signs and Symptoms in Patients with Constipation

1. Hematochezia
2. Melena
3. Family history of colon cancer
4. Family history of inflammatory bowel disease
5. Anemia
6. Weight loss
7. Anorexia
8. Nausea and vomiting
9. Severe, persistent constipation that is refractory to treatment
10. New onset or worsening of constipation in elderly patients without evidence of a possible primary cause

bulk-forming laxatives and dietary fiber with occasional use of saline or stimulant laxatives). Patients with alarm symptoms, with a family history of colon cancer, or those >50 years old with new symptoms may need further diagnostic evaluation. Table 43–10 presents a general treatment algorithm for the management of constipation.

6 The proper management of constipation requires a number of different modalities; however, the basis for therapy should be dietary modification in most cases. The major dietary change should be an increase in the amount of fiber consumed daily. In addition to dietary management, patients should be encouraged to alter other aspects of their lifestyle if necessary. Important considerations are to encourage patients to exercise (achieved even by brisk walking after dinner) and to adjust bowel habits so that a regular and adequate time is made to respond to the urge to defecate. Another general measure is to increase fluid intake. This is generally recommended and believed beneficial, although there is little objective evidence to support this measure.

TABLE 43-10 Constipation Treatment Algorithm

History
- Stool frequency
- Stool consistency
- Difficulty of defecation

Possible causes
- Diet deficient in high-fiber items and consisting mainly of highly refined foods
- GI disorders
- Metabolic and endocrine disorders
- Pregnancy
- Neurogenic
- Psychogenic
- Drug induced
- Laxative abusers

Symptoms seen with chronic constipation
- Fluid and electrolyte imbalances (hypokalemia)
- Protein-losing gastroenteropathy with hypoalbuminemia
- Syndromes resembling colitis

Select appropriate diagnostic studies
- Proctoscopy
- Sigmoidoscopy
- Colonoscopy
- Barium enema

Diagnosis
1. Treat specific cause
2. No diagnosis, symptomatic therapy
   A. Bulk-forming agents
   B. Dietary modification
   C. Alter lifestyle (exercise)
   D. Increase fluid intake
   F. Discontinue potential drug inducer

If an underlying disease is recognized as the cause of constipation, attempts should be made to correct it. GI malignancies may be removed via surgical resection. Endocrine and metabolic derangements should be corrected by the appropriate methods. For example, when hypothyroidism is the cause of constipation, cautious institution of thyroid-replacement therapy is the most important treatment measure.

As discussed earlier, many drug substances may cause constipation. If a patient is consuming medications well known to cause constipation, consideration should be given to alternative agents. For some medications (e.g., antacids), nonconstipating alternatives exist. If no reasonable alternatives exist to the medication thought to be responsible for constipation, consideration should be given to lowering the dose. If a patient must remain on constipating medications, then more attention must be given to general measures for prevention of constipation, as discussed in the next section.

NONPHARMACOLOGIC THERAPY

Dietary Modification and Bulk-Forming Agents

The most important aspect of therapy for constipation for the majority of patients is dietary modification to increase the amount of fiber consumed. Fiber, the portion of vegetable matter not digested in the human GI tract, increases stool bulk, retention of stool water, and rate of transit of stool through the intestine. The result of fiber therapy is an increased frequency of defecation. Also, fiber decreases intraluminal pressures in the colon and rectum, which is thought to be beneficial for diverticular disease and for IBS. The specific physiologic effects of fiber are not well understood. Patients should be advised to gradually increase daily fiber intake to 20 to 25 grams, either through dietary changes or fiber supplement products.[30] Fruits, vegetables, and cereals typically have the highest fiber content. Bran, a by-product of milling of wheat, is often added to foods to increase fiber content and contains a high amount of soluble fiber, which may be extremely constipating in larger doses. Raw bran is generally 40% fiber. Medicinal products, often called "bulk-forming agents," such as psyllium hydrophilic colloids, methylcellulose, or polycarbophil, have properties similar to those of dietary fiber and may be taken as tablets, powders, or granules.

A trial of dietary modification with high-fiber content should be continued for at least 1 month before effects on bowel function are determined. Most patients begin to notice effects on bowel function 3 to 5 days after beginning a high-fiber diet, but some patients may require a considerably longer period of time. Patients should be cautioned that abdominal distension and flatus may be particularly troublesome in the first few weeks of fiber therapy, particularly with high bran consumption. Gradually increasing dietary fiber over a few weeks to the goal of 20 to 25 grams may help reduce some of the adverse abdominal effects. In most cases these problems resolve with continued use.

Bulk-forming laxatives have few adverse effects. The only major caution in the use of bulk-forming laxatives is that obstruction of the esophagus, stomach, small intestine, and colon has been reported when the agents have been consumed without sufficient fluid and in patients with intestinal stenosis.

Surgery

In a small percentage of patients who present with complaints of constipation, surgical procedures are necessary because of the presence of colonic malignancies or GI obstruction from a number of other causes. In each case, the involved segment of intestine may be resected or revised. Surgery may be required in some endocrine

disorders that cause constipation, such as pheochromocytoma, which requires removal of a tumor.

Biofeedback

Patients with constipation due to pelvic floor dysfunction/disordered defecation may have a less favorable response to fiber therapy than other constipation subtypes.[34] Many adult patients with functional defecatory disorders appear to benefit from pelvic floor retraining with biofeedback therapy. Success rates of 65–80% have been reported in controlled and uncontrolled studies.[35] The value of biofeedback in children with chronic constipation has not been well demonstrated.[36]

PHARMACOLOGIC THERAPY

Drug Regimens of Choice

For most patients, treatment and prevention of constipation should consist of bulk-forming agents in addition to dietary modifications that increase dietary fiber.[30,37] A variety of products are available that provide adequate bulk. Whichever agent is chosen, it should be used daily and continued indefinitely in most patients, particularly those with chronic constipation.

For most persons with acute constipation, infrequent use (less than every few weeks) of laxative products is acceptable. Acute constipation may be relieved by the use of a tap-water enema or a glycerin suppository; if neither is effective, the use of oral sorbitol, low doses of bisacodyl or senna, low-dose polyethylene glycol (PEG) (Miralax), or saline laxatives (e.g., milk of magnesia) may provide relief. If laxative treatment is required for longer than 1 week, the person should be advised to consult a physician to determine if there is an underlying cause of constipation that requires treatment with other modalities.

For bedridden or geriatric patients, or others with chronic constipation, bulk-forming laxatives remain the first line of treatment, but the use of more potent laxatives may be required relatively frequently. When other than bulk-forming laxatives are used, they should be administered in the lowest effective dose and as infrequently as possible to maintain regular bowel function (more than three stools per week). Agents that may be used in these situations include "osmotic" laxatives such as sorbitol, lactulose, low-dose PEG, or perhaps milk of magnesia (magnesium hydroxide). "Stimulant" laxatives such as senna and bisacodyl may also be used but because these agents can have a less desirable side effect profile, they may be reserved for patients who fail to respond to osmotic laxatives and increased daily fiber.[30,38] Mineral oil should be avoided, particularly in bedridden patients, because of the risk of aspiration and lipoid pneumonia. Some patients with chronic constipation may present with fecal impactions. Before vigorous oral laxatives can be used, the impaction needs to be removed using mechanical methods, including tap-water or saline enemas and digital extraction.

In the hospitalized patient without GI disease, constipation may be related to the use of general anesthesia and/or opiate substances. Most orally or rectally administered laxatives may be used in these situations. For prompt initiation of bowel evacuation, either a tap-water enema, glycerin suppository, or oral milk of magnesia is recommended. Several new agents that are peripheral opioid-receptor antagonists may be used in specific patient populations (postsurgical, hospitalized, and/or palliative care patients receiving chronic opioid therapy).

With infants and children, constipation may occur commonly. In patients with persistent problems, the underlying etiology may be neurologic, metabolic, or secondary to anatomic abnormalities. Management of constipation in this age group should consist of dietary modification with an emphasis on high-fiber foods or treatment of underlying cause. For acute constipation in most age groups, a tap-water enema or glycerin suppository may be helpful. Occasional use of osmotic or stimulant laxatives in low doses is justified as well.

TABLE 43-11 Dosage Recommendations for Laxatives and Cathartics

Agent	Recommended Dose
Agents that cause softening of feces in 1–3 days	
Bulk-forming agents/osmotic laxatives	
Methylcellulose	4–6 g/day
Polycarbophil	4–6 g/day
Psyllium	Varies with product
Polyethylene glycol 3350	
Emollients	
Docusate sodium	50–360 mg/day
Docusate calcium	50–360 mg/day
Docusate potassium	100–300 mg/day
Lactulose	15–30 mL orally
Sorbitol	30–50 g/day orally
Mineral oil	15–30 mL orally
Agents that result in soft or semifluid stool in 6–12 h	
Bisacodyl (oral)	5–15 mg orally
Senna	Dose varies with formulation
Magnesium sulfate (low dose)	<10 g orally
Agents that cause watery evacuation in 1–6 h	
Magnesium citrate	18 g 300 mL water
Magnesium hydroxide	2.4–4.8 g orally
Magnesium sulfate (high dose)	10–30 g orally
Sodium phosphates	Varies with salt used
Bisacodyl	10 mg rectally
Polyethylene glycol–electrolyte preparations	4 L

Drug Classes

The traditional classification system for laxatives and cathartics by suspected mode of action may not be very useful, as the mode of action is not clearly understood for many agents. In general, most of these products induce bowel evacuation by one or more of the mechanisms associated with the etiology of diarrhea, including active electrolyte secretion, decreased water and electrolyte absorption, increased intraluminal osmolarity, and increased hydrostatic pressure in the gut. Laxatives convert the intestine from primarily an organ that absorbs water and electrolytes to an organ that secretes these substances. Identification of laxative agents by traditional classification system however, is important as this nomenclature is often used by other healthcare practitioners and in the medical literature (Table 43–11).

The three general classes of laxatives are discussed in this section: (a) those causing softening of feces in 1 to 3 days (bulk-forming laxatives, docusates, the poorly absorbable sugars (lactulose and sorbitol), and low-dose PEG; (b) those that result in soft or semifluid stool in 6 to 12 hours (diphenylmethane derivatives and anthraquinone derivatives; "stimulant-type" laxatives); and (c) those causing water evacuation in 1 to 6 hours (saline cathartics, castor oil, and high-dose polyethylene glycol-electrolyte lavage solution).

Emollient Laxatives

Emollient laxatives are surfactant agents, docusate in its various salts, which work by facilitating mixing of aqueous and fatty materials within the intestinal tract. They may increase water and electrolyte secretion in the small and large bowel. Increased stool moisture content should lead to a softer, easier-to-pass stool. These products are generally given orally, although docusate potassium has also

been used rectally. With these products, softening of stools occurs within 1 to 3 days of therapy.

Emollient laxatives are ineffective in treating constipation but are used mainly to prevent this condition. They may be helpful in situations in which straining at stool should be avoided, such as after recovery from myocardial infarction, with acute perianal disease, or after rectal surgery. It is unlikely that these agents would be effective in preventing constipation if major causative factors (e.g., heavy opiate use, uncorrected pathology, or inadequate dietary fiber) are not concurrently addressed.

Although docusates are generally safe, a few adverse effects have been noted. They may increase the intestinal absorption of agents administered concurrently and alter toxic potential. Reports of increased fecal soiling associated with docusate use in elderly patients may limit their use in this population.[38]

Mineral Oil

Mineral oil is the only lubricant laxative in routine use. This agent, obtained from petroleum refining, acts by coating stool and allowing for easier passage. It inhibits colonic absorption of water, thereby increasing stool weight and decreasing stool transit time. Mineral oil may be given orally or rectally in a dose of 15 to 45 mL. Generally, the effect on bowel function is noted after 2 or 3 days of use.

Mineral oil is helpful in situations similar to those suggested for docusates: to maintain a soft stool and to avoid straining for relatively short periods of time (a few days to 2 weeks); however, it possesses a much greater potential for adverse effects, and its routine use should be discouraged. Mineral oil may be absorbed systemically and can cause a foreign-body reaction in lymphoid tissue. Also, in debilitated or recumbent patients, mineral oil may be aspirated, causing lipoid pneumonia.[30,38] Mineral oil may decrease the absorption of fat-soluble vitamins (A, D, E, and K) with chronic use by causing retention in the GI tract. Finally, even when given orally, mineral oil may leak from the anal sphincter, causing pruritus and soiling of clothing.

Lactulose and Sorbitol

Lactulose is a nonabsorbable disaccharide that is used orally or rectally. It is metabolized by colonic bacteria to low-molecular-weight acids, resulting in an osmotic effect whereby fluid is retained in the colon. The fluid retained in the colon lowers the pH and increases colonic peristalsis. Lactulose increases stool frequency and consistency in patients with chronic constipation (vs. placebo) and may be more effective than fiber alone. Head-to-head studies suggest that lactulose is slightly less effective than low-dose PEG or some combination laxative agents (such as those containing fiber plus senna–not currently available in the United States). Lactulose is generally not recommended as a first-line agent for the treatment of constipation because it is costly, requires a prescription, and is associated with adverse effects such as flatulence, nausea, and abdominal discomfort or bloating–though it can be useful in some patients. It may be justified as an alternative for acute constipation or in patients with an inadequate response to increased dietary fiber and bulking agents. In some patients with more complex disease or nonmodifiable risk factors for constipation (such as beridden, elderly patients with chronic or debilitating illnesses and constipating medications), lactulose may be required on a more regular basis. In addition to the adverse abdominal effects associated with lactulose, diarrhea and electrolyte imbalances can occasionally occur.[38] Sorbitol, a monosaccharide, also exerts its effect by osmotic action and has been recommended as a cost-effective alternative to lactulose. It is as effective as lactulose but may cause less nausea and is much less expensive.[37,38]

Diphenylmethane and Anthraquinone Derivatives

Bisacodyl, the only remaining diphenylmethane derivative with the withdrawal of phenolphthalein, exerts its therapeutic effect by stimulating the mucosal nerve plexus of the colon and may also affect intestinal fluid secretion by altering fluid and electrolyte transport. Bisacodyl exhibits significant interpatient variability in effective dose, with doses that cause no effect in one patient or resulting in excessive cramping and fluid evacuation in others. Bisacodyl is generally reserved for intermittent use (every few weeks) to treat constipation or as a bowel preparation before diagnostic procedures in which cleansing of the colon is necessary. It may be adminstered orally or as a suppository, both recommended once daily. Bisacodyl may sometimes cause severe abdominal cramping as well as significant fluid and electrolyte imbalances with chronic use.

Senna or sennosoids are the only remaining anthraquinone derivatives after removal of cascara sagrada and casanthrone (cascara extracts). Laxative effects are limited to the colon, and stimulation of the Auerbach plexus may be involved. As with bisacodyl, senna is only generally recommended for intermittent use. Senna-containing products are given orally.

In the past, clinicians have hesitated to use stimulant-type laxatives on a regular basis due to claims that the colon was harmed by chronic use. Stimulant laxatives were thought to cause cathartic colon, damage the enteric nervous system, and lead to a physical dependence on laxatives for defecation. There is little evidence that stimulant laxatives given in appropriate doses (not more than once daily) cause intestinal/enteric damage or physical dependency (the role of psychological dependency is a separate issue discussed in the laxative abuse section).[30] Excessive use or abuse of stimulant laxatives, however, is a concern with these agents and can result in large-volume watery diarrhea, fluid loss, and electrolyte disturbances. Melanosis coli, a change in colon pigmentation with chronic anthraquinone therapy once thought to be linked to colon cancer, is now known to be a benign and reversible condition. Though safety may be of less concern than previously thought, because of their risk of adverse effects (abdominal cramping and fluid/electrolyte imbalance), stimulants are typically reserved for intermittent use or in patients who fail to respond adequately to bulking and osmotic laxatives. However, some patients with severe chronic constipation and nonmodifiable risk factors may use these agents on a more regular basis.

Saline Cathartics

Saline cathartics are composed of relatively poorly absorbed ions such as magnesium, sulfate, phosphate, and citrate, which produce their effects primarily by osmotic action causing retention of fluid in the GI tract. Magnesium also stimulates the secretion of cholecystokinin, a hormone that causes stimulation of bowel motility and fluid secretion. These agents may be given orally or rectally. A bowel movement may result within a few hours after oral doses and in 1 hour or less after rectal administration.

These agents should be used primarily for acute evacuation of the bowel, which may be necessary before diagnostic examinations, after poisonings, and in conjunction with some anthelmintics to eliminate parasites. Such agents as milk of magnesia (an 8% suspension of magnesium hydroxide) may be used occasionally (every few weeks) to treat constipation in otherwise healthy adults. Saline cathartics should not be used on a routine basis. The enema formulations of these agents may be useful in fecal impactions.

As with most laxatives, these agents may cause fluid and electrolyte depletion. Also, magnesium or sodium accumulation may occur when magnesium-containing cathartics are used in patients

with renal dysfunction or when sodium phosphate is used in patients with congestive heart failure. These risks increase with long-term use.

Castor Oil

Castor oil is metabolized in the GI tract to an active compound, ricinoleic acid, which stimulates secretory processes, decreases glucose absorption, and promotes intestinal motility, primarily in the small intestine. Castor oil usually results in a bowel movement within 1 to 3 hours of administration. Because the agent has such a strong purgative action, it should not be used for the routine treatment of constipation.

Glycerin

Glycerin is usually administered as a 3 g suppository and exerts its effect by osmotic action in the rectum. As with most agents given as suppositories, the onset of action is usually less than 30 minutes. Glycerin is considered a safe laxative, although it may occasionally cause rectal irritation. Its use is acceptable on an intermittent basis for constipation, particularly in children.

Polyethylene Glycol-Electrolyte Lavage Solution

Whole-bowel irrigation with polyethylene glycol-electrolyte lavage solution (PEG-ELS) has become popular for colon cleansing before diagnostic procedures or colorectal operations. Various preparations are available (of varying molecular weights) with and without electrolytes.

Four liters of this solution is administered over 3 hours to obtain complete evacuation of the GI tract. The lavage solution is not recommended for routine treatment of constipation, and its use should be avoided in patients with intestinal obstruction.

Low doses of PEG, however, are FDA-approved for treatment of constipation. For this indication, PEG is administered in smaller volumes (10–30 g or 17–34 g per 120–240 mL) usually once (or twice) daily. With lesser volumes and slower ingestion, PEG has a much lower incidence of the adverse abdominal effects or electrolyte disturbances associated with whole-bowel lavage. PEG may also have fewer side effects than other "osmotic" agents because it is not absorbed systemically or metabolized by colonic bacteria.[39] PEG has been safely tolerated even when used for longer durations of therapy (up to 6 months). PEG was first approved as a prescription laxative for occasional constipation in 1999. In 2006, PEG 3350 gained FDA approval for nonprescription treatment of occasional constipation under the brand name Miralax.

Lubiprostone

Lubiprostone is the first new drug in a class called "chloride channel activators," which are designed to act locally in the gut to open chloride channels on the GI luminal epithelium, which, in turn, stimulates chloride-rich fluid secretion into the intestinal lumen. Increased intraluminal fluid secretion helps to soften stool and accelerate GI transit time.[40] Lubiprostone (Amitiza) was first approved in 2006 for "chronic idiopathic constipation in adults" at a recommended dose of one 24 mg capsule twice daily with food. In 2008, Lubiprostone also received FDA approval for treatment of patients with constipation-predominant irritable bowel sydnrome (IBS-C). Clinical trials have shown a significant increase in spontaneous bowel movements in patients treated with lubiprostone versus placebo as well as improvement in straining, stool consistency, and overall constipation severity.[41] For most patients, bowel movements occur within 24 to 48 hours of lubiprostone administration. Common adverse effects include headache (13%), diarrhea, and nausea.[40] Because of its high cost (especially relative to other available laxative agents) and lack of comparative data with other laxative therapies, lubiprostone will likely be reserved for patients with chronic constipation that fail conventional first-line agents.

Prucalopride

Prucalopride is a selective 5 hydroxytriptamine-4 (5HT-4) receptor agonist being developed for treatment of chronic constipation and IBS-C. Prucalopride demonstrates proenterokinetic effects (increased colonic motility and transit), specifically in the GI tract. Prucalopride, however, is more selective than the previously available serotonergic agonist cisapride and tegaserod with higher affinity for the 5HT-4 receptor. Receptor selectivity is thought to improve the safety profile of prucalopride over cisapride and tegaserod, which were removed from the market due to concerns for adverse cardiovascular events. In clinical trials, prucalopride significantly increased the number of complete, spontaneous bowel movements in adults with chronic constipation.[42] Constipation symptoms and quality of life were also improved with prucalopride. This agent has been safely tolerated in clinical trials with no adverse cardiovascular effects versus placebo (though data are limited). Prucalopride has not yet been approved by the FDA.

Opioid-Receptor Antagonists

Alvimopan (Entereg) is an oral gastrointestinal-specific mu-receptor antagonist approved for short-term use in hospitalized patients to accelerate recovery of bowel function after large or small bowel resection. Causes of postoperative ileus are multifactorial, with the effects of opioids considered to be a significant contributing factor. Alvimopam antagonizes the GI (peripheral) effects of opioids without affecting analgesia because it does not cross the blood-brain barrier. Alvimopan is only available through a special use program (ENTEREG access support and education; EASE), which requires hospitals to register and meet all requirements before the drug can be administered. Additionally, alvimopan is contraindicated in patients receiving therapeutic doses of opioids for more than seven consecutive days prior to surgery (as they may be more sensitive to the drug's effects). Dosing for alvimopan is as follows: 12 mg capsule adminstered 30 min to 5 hours before surgery and then 12 mg twice daily for up to 7 days or until discharge (maximum of 15 doses).

Methylnaltrexone (Relistor) is mu receptor-antagonist approved for opioid-induced constipation in patients with advanced disease receiving palliative care or when response to laxative therapy has been insufficient. This agent does not cross the blood-brain barrier or antagonize analgesia; it acts on peripheral mu receptors to antagonize unwanted opioid side effects such as constipation. It is administered at a weight-based dose as a subcutaneous injection, usually every other day (no more than once daily), and is contraindicated in patients with known or suspected gastrointestinal obstruction.

Naltrexone and naloxone are opioid antagonists but are not used in constipation because they do cross the blood-brain barrier and reverse CNS effects of opioids (respiratory depression and analgesia).

Other Agents

Tap-water enemas may be used to treat simple constipation. The administration of 200 mL of tap water by enema to an adult often results in a bowel movement within 30 minutes. Soap-suds enemas are no longer recommended as their use may result in proctitis or colitis.

Prevention

For certain groups of patients, such as those recovering from myocardial infarction or rectal surgery, straining at defecation is to be avoided. The basis of preventive therapy in these patients should be bulk-forming laxatives. Additionally, the use of docusate is popular, although its effectiveness is debated. In pregnant patients, constipation may result because of alterations in anatomy or iron supplementation. As described earlier, bulk-forming laxatives and docusates should be the first line of prevention.

LAXATIVE ABUSE SYNDROME

Misconceptions about normal bowel patterns and the effect of laxatives have contributed to a syndrome of laxative abuse that is relatively common in the United States. The availability of laxatives over the counter and as chocolates or gums conveys to the public that the use of these agents is without adverse consequences. Abuse of laxatives has occurred traditionally in persons trying to maintain daily bowel function, but has extended to others who use laxatives for the purpose of controlling weight. In either case, the consistent abuse of strong laxatives and cathartics may lead to serious illness.

Laxative abuse for the purpose of maintaining daily bowel function begins with misconceptions about the frequency, quantity, or consistency of stools. With the use of strong purgatives, the colon may be so thoroughly cleansed that a bowel movement may not occur normally until a few days later. This delay reinforces the need for more purgatives, and the cycle of laxative dependence is begun. Eventually the patient may require daily laxatives to maintain bowel function. A variation of laxative abuse is seen in persons who use them as a means of weight loss.

The laxative abuser may present with contradictory findings of diarrhea and weight loss. In addition, long-term abusers of laxatives tend to have vomiting, abdominal pain, lassitude, weakness, thirst, edema, and bone pain (caused by osteomalacia). With prolonged use of laxatives a number of serious illnesses may arise, including fluid and electrolyte imbalances (e.g., acid-base imbalances and hypokalemia), protein-losing gastroenteropathy with hypoalbuminemia, and syndromes resembling colitis.

The determination of laxative abuse syndrome can be difficult because many laxative abusers vigorously deny laxative use. Middle-aged women tend to be the most common laxative abusers. The chronic laxative abuse problem should be addressed by a combination of measures, including psychiatric evaluation, dietary modification with reliance on bulk-forming laxatives, and specific guidelines to the patient for the withdrawal of stimulant laxatives.

EVALUATION OF THERAPEUTIC OUTCOMES

The ultimate goal of treatment for constipation is alteration of lifestyle (particularly diet) and modifiable secondary causes (drugs, etc.) to prevent further episodes of constipation. Short-term goals include alleviation of acute constipation with relief from symptoms. For patients with chronic constipation, the goals are more long term and include use of proper diet and decreased reliance on laxatives in addition to relief of symptoms for the patient so that quality of life is not diminished. Effective treatment of constipation requires the patient to become more knowledgeable about the causes of constipation, proper diet, and appropriate use of laxatives.

IRRITABLE BOWEL SYNDROME

IBS is a gastrointestinal syndrome characterized by chronic abdominal pain and altered bowel habits in the absence of any organic cause. It is the most commonly diagnosed gastrointestinal condition.

EPIDEMIOLOGY

The prevalence of IBS is approximately 10% to 15% based on North American and European population-based studies; however, there is a wide variation in prevalence by individual country.[43–46] IBS affects men and women, young patients, and the elderly with an overall 2:1 female predominance in North America.[45] However, younger patients and women are more likely to be diagnosed with IBS. Although only 15% of those affected actually seek medical attention, IBS is the cause of between 25% and 50% of all referrals to gastroenterologists.[43]

PATHOPHYSIOLOGY

Although the exact pathophysiologic abnormalities with IBS are still being actively investigated, IBS likely results from altered somatovisceral and motor dysfunction of the intestine from a variety of causes. Abnormal central nervous system processing of afferent signals may lead to visceral hypersensitivity, with the specific nerve pathway affected determining the exact symptomatology expressed. This visceral hypersensitivity is a neuroenteric phenomenon that is independent of motility and psychological disturbances.[47] Factors known to contribute to these alterations include genetics, motility factors, inflammation, colonic infections, mechanical irritation to local nerves, stress, and other psychological factors.

Serotonin-Type Receptors

The enteric nervous system contains a significant percentage of the body's 5-hydroxytryptamine (serotonin, 5-HT).[48] Two types of serotonin exist within the gut: serotonin type 3 (HT_3) and serotonin type 4 (HT_4), which are responsible for secretion, sensitization, and motility.[49] There is an increase in the postprandial levels of 5-HT in those who suffer from diarrhea-predominant IBS when compared with nonsufferers.[48] Therefore, stimulation and antagonism of these serotonin receptors have become a focused area for research on new drug therapies for both diarrhea- and constipation-predominant disease.

CLINICAL PRESENTATION

7 IBS presents as either diarrhea-predominant or constipation-predominant disease and can be defined as lower abdominal pain, disturbed defecation (constipation, diarrhea, or an alternating pattern of both), and bloating in the absence of structural or biochemical factors that might explain these symptoms (Table 43–12).

TABLE 43-12 Clinical Presentation of Irritable Bowel Syndrome

Signs and symptoms
• Lower abdominal pain
• Abdominal bloating and distension
• Diarrhea symptoms, >3 stools/day
• Extreme urgency
• Passage of mucus
• Constipation symptoms, <3 stools/wk, straining, incomplete evacuation
• Psychological symptoms such as depression and anxiety
Nongastrointestinal symptoms
• Urinary symptoms
• Fatigue
• Dyspareunia
Other concurrent conditions
• Fibromyalgia
• Functional dyspepsia
• Chronic fatigue syndrome
Reduced health-related quality of life

TABLE 43-13 Symptom-Based Criteria for Irritable Bowel Syndrome

The manning criteria[50]

Chronic or recurrent abdominal pain for at least 6 months and two or more of the following:

1. Abdominal pain relieved with defecation
2. Abdominal pain associated with more frequent stools
3. Abdominal pain associated with looser stools
4. Abdominal distension
5. Feeling of incomplete evacuation after defecation
6. Mucus in stools

Rome III diagnostic criteria for irritable bowel syndrome[27]

Recurrent abdominal pain or discomfort at least 3 days per month in the last 3 months associated with two or more of the following:

1. Relieved with defecation
2. Onset associated with a change in frequency of stool
3. Onset associated with a change in form (appearance) of stool

Because IBS can consist of a variable number of signs and symptoms, two diagnostic criteria "check lists" are commonly used to aid in the workup of a patient suspected of having IBS. The Manning criteria were first proposed in 1978, whereas the Rome criteria were initially proposed in 1999 and revised as recently as 2006 by an international working group in an effort to help standardize the diagnostic criteria used in clinical research protocols. Table 43–13 shows the symptom criteria for both of the Manning[50] and Rome III[27] symptom-based criteria.

Additional diagnostic steps that can be taken include sigmoidoscopy or colonoscopy; examination of the stool for occult blood and ova and parasites; complete blood cell count; erythrocyte sedimentation rate; and serum electrolytes. In some cases, radiographic imaging studies, such as computed tomography scans or barium swallows or enemas, may also be necessary if the findings of the foregoing assessment are not typical for IBS.[43]

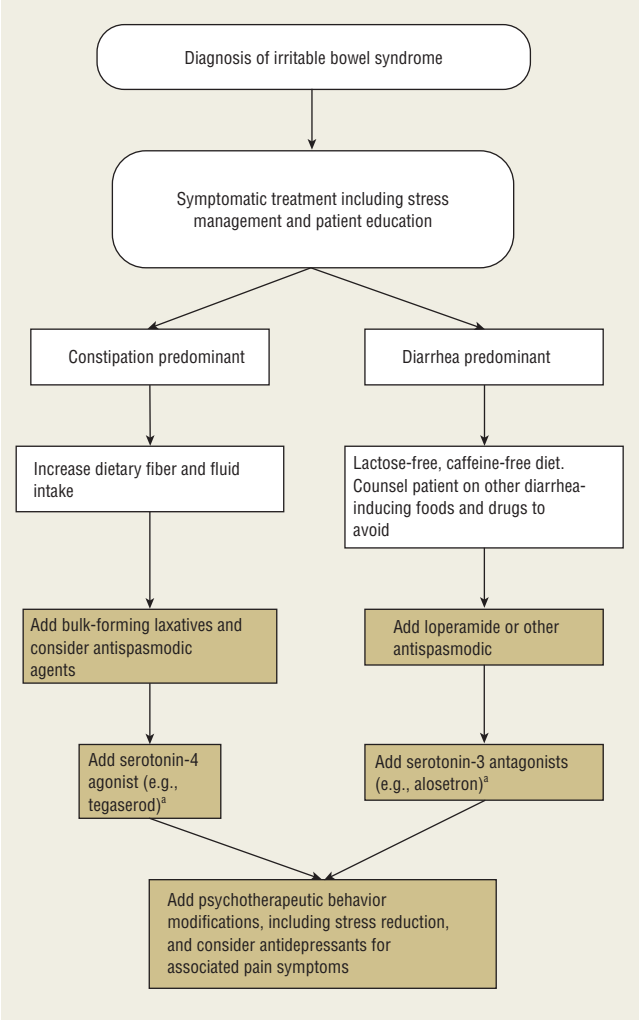

FIGURE 43-3. A general stepwise approach to the management of both constipation- and diarrhea-predominant irritable bowel syndrome. [a]Consider manufacturer sponsored patient access program.

TREATMENT

Irritable Bowel Syndrome

GENERAL APPROACH TO TREATMENT

The treatment approach to IBS is based upon the predominant symptoms and their severity (Fig. 43–3). Milder, less frequent episodes can be managed with dietary restrictions and a higher-fiber diet, with addition of bulk-forming laxatives, if necessary. More persistent disease may require as-needed uses of various antispasmodic or antidiarrheal agents such as loperamide. Lastly, the most-severe forms of this disease may call for pharmacologic agents directed specifically at the underlying neurohormonal imbalance, such as the 5-HT_4 agonists (e.g., tegaserod), or the 5-HT_3 receptor antagonists (e.g., alosetron).

Alosetron, a 5-HT_3 receptor antagonist, was withdrawn from the U.S. market in 2000 as a result of serious adverse effects, including severe constipation and ischemic colitis that did not appear in the initial clinical trials. It was reintroduced in 2002 and is now limited to an FDA-approved restricted-use program in lower initial doses, and requires extensive postmarketing surveillance. Results of these trials are necessary to definitively determine alosetron's true safety profile, especially with regard to its association with or causation of fatal ischemic colitis.

CONSTIPATION-PREDOMINANT DISEASE

In the constipation-predominant patient, dietary fiber may be beneficial. Patients should be instructed to begin with 1 tablespoonful of fiber with one meal daily and gradually increase the dose to include fiber with two and three meals a day until the desired outcome is achieved. End points that the patient should aim for include bulkier and more easily passed stools. For patients unable to tolerate dietary bran, bulking agents such as psyllium may be substituted.[51] Laxative use is not encouraged in these patients, and it should only be used in the smallest dose for the least amount of time in cases of severe constipation.

The 5-HT_4 partial agonist tegaseride was the first therapy approved by the FDA specifically for short-term, intermittent treatment of IBS-C.[52] Tegaseride was suspended from marketing in early 2007 at the request of the FDA due to an analysis of clinical trial data showing a small, yet significant, increase in ischemia events (MI, cerebrovascular accident (CVA), and unstable angina) in patients with preexisting cardiovascular disease and/or cardiovascular risk factors. In July 2007, the drug's manufacturer, Novartis, began a tegaseride (Zelnorm) restricted-access program for patients in the United States. Tegaseride is a serotonin derivative that activates 5-HT_4 receptors on the neurons in the gastrointestinal tract, increasing GI motility and decreasing visceral sensations. It is approved as 2 mg or 6 mg doses given twice

daily 30 minutes prior to a meal with water for up to 12 weeks.[53] Stimulation of the 5-HT_4 receptors by tegaseride increases gastric secretions and promotes motility, with improvement in symptoms generally occurring within the first week of therapy. Currently this therapy is only approved for use in women; efficacy and safety in men have not been established because of inadequate numbers of men enrolled in clinical trials to date.[54] Diarrhea was the most common adverse effect, resulting in drug discontinuation in 1.6% of study subjects.

CLINICAL CONTROVERSY

The newer serotonin receptor agonists and antagonists tegaserod and alosetron act on GI-specific serotonin receptors to treat constipation-predominant and diarrhea-predominant IBS, respectively. However, both drugs are currently only indicated for women. Efficacy and safety in men have not been established because the initial manufacturer's sponsored clinical trials contained insufficient numbers of men with IBS to provide the necessary statistical power to prove efficacy and safety. Ongoing studies should determine whether these drugs are indicated in men.

DIARRHEA-PREDOMINANT DISEASE

8 For patients in whom diarrhea is the primary complaint, avoidance of certain food products may be necessary. Caffeine, alcohol, and artificial sweeteners (sorbitol, fructose, and mannitol) are known to irritate the gut and produce a laxative effect. Lactose intolerance should be considered in certain patients; however, the prevalence of this condition may be exaggerated.

Herbal medicines or teas often contain senna, which may produce diarrhea. In patients with disease persistence following dietary modification, loperamide may be used for episodic management of urgent diarrhea, or in situations in which the patient wishes to avoid the possibility of an acute onset of symptoms.[53] Loperamide decreases intestinal transit, enhances water and electrolyte absorption, and strengthens rectal sphincter tone. Some patients may require continuous therapy, and careful dosage titration can usually be undertaken to prevent the development of constipation.

Diarrhea-predominant IBS caused by excessive stimulation of the 5-HT_3 receptor can be relieved by the drug alosetron. Alosetron was the first effective treatment for diarrhea-predominant IBS.[55] However, in November 2000 it was voluntarily withdrawn from the market because of severe GI adverse effects, including 113 reported cases of serious constipation and 8 cases of possible ischemic colitis and death. This decision was met with a great public outcry, as many who had suffered for years had experienced relief for the first time. Because this drug was highly effective in many patients, the FDA approved restricted use of alosetron in June 2002. Alosetron is now available via an FDA-approved restricted-use program in conjunction with GlaxoSmithKline as detailed at *http://www.lotronex.com*. It is now indicated, in lower initial doses of 0.5 mg twice daily, for women with diarrhea-predominant symptoms of longer than 6 months' duration that are not relieved by conventional therapy. Healthcare providers must use extreme caution in therapy with this drug and must follow strict FDA-mandated guidelines.

Probiotics (see earlier Diarrhea) such as *Lactobacillus* and *Bifidobacterium* reduced IBS symptoms in several investigative trials.[17] Another 5-HT_3 antagonist, cilansetron, has demonstrated efficacy similar to that of alosetron in phase II trials and enrolled enough male patients to show benefit in males as well.[55]

Use of Antidepressants in Irritable Bowel Syndrome

Tricyclic antidepressants have shown some benefit in treatment of diarrhea-predominant IBS associated with moderate to severe abdominal pain, by modulating perception of visceral pain, altering GI transit time, and treating underlying comorbidities.[56,57] Selective serotonin reuptake inhibitors are less-well studied, with only one report with paroxetine showing some improvement in stool passage and "well-being" but no decrease in abdominal pain.[58–60]

Figure 43–3 shows a general stepwise approach to the management of both constipation and diarrhea-predominant IBS.

PAIN IN IRRITABLE BOWEL SYNDROME

9 Some patients with IBS suffer significant pain associated with their disease. Data supporting the use of antispasmodic agents in these patients are conflicting.[43] A trial of low-dose antidepressant therapy is indicated, especially if pain is associated with eating. Both tricyclic antidepressants and serotonin reuptake inhibitors produce analgesia and may relieve depressive symptoms if present. Preprandial doses of drugs containing anticholinergic properties may suppress pain (and/or diarrhea) associated with an overactive postprandial gastrocolonic response. Tricyclic antidepressants should be avoided in patients with pain and constipation. In addition, psychotherapy, including cognitive behavioral therapy, relaxation therapy, and hypnotherapy, has been shown to decrease IBS symptoms.[61]

EVALUATION OF THERAPEUTIC OUTCOMES

IBS is usually classified as constipation-predominant, diarrhea-predominant, or IBS with abdominal pain and bloating. Therapeutic goals in IBS should focus on the patient's primary complaint. Dietary and drug therapy goals should focus on end-organ treatment to relieve abdominal pain (antispasmodic drugs) or disturbed bowel habits (antidiarrheals and bulk-forming agents). Additionally, severe symptoms from central nervous system dysregulation should be treated with antidepressants, psychotherapy, relaxation/stress management, cognitive behavior treatment, and/or hypnosis aimed at specific affective disorders.[43] Lastly, the serotonin receptor agonists and antagonists can be used in carefully selected patients whose symptoms are not adequately controlled with other agents. The American Gastroenterology Association recommends that patients with severe IBS consider psychological treatments such as psychotherapy, relaxation/stress management, and/or cognitive behavior treatment.

ABBREVIATIONS

AGA: American Gastroenterology Association

AIDS: acquired immunodeficiency syndrome

CDC: Centers for Disease Control and Prevention

CVA: Cerebrovascular Accident

5-HT: serotonin

IBS: irritable bowel syndrome

IBS-C: constipation-predominant irritable bowel syndrome

ORS: oral rehydration solution

PEG-ELS: polyethylene glycol-electrolyte lavage solution

PHM: peptide histidine methionine

VIP: vasoactive intestinal peptide

CHAPTER 44

Portal Hypertension and Cirrhosis

JULIE M. SEASE

KEY CONCEPTS

1. Cirrhosis is a severe, chronic, irreversible disease associated with significant morbidity and mortality. However, the progression of cirrhosis secondary to alcohol abuse can be interrupted by abstinence. It is therefore imperative for the clinician to educate and support abstinence from alcohol as part of the overall treatment strategy of the underlying liver disease.
2. Patients with cirrhosis should receive endoscopic screening for varices, and certain patients with varices should receive primary prophylaxis with nonselective β-adrenergic blockade therapy to prevent variceal hemorrhage.
3. When nonselective β-adrenergic blocker therapy is used to prevent rebleeding, β-blocker therapy can be titrated to achieve a goal heart rate of 55 to 60 beats per minute or the maximal tolerated dose.
4. Octreotide is the preferred vasoactive agent for the medical management of variceal bleeding. Endoscopy employing endoscopic band ligation is the primary therapeutic tool for the management of acute variceal bleeding.
5. The combination of spironolactone and furosemide is the recommended initial diuretic therapy for patients with ascites.
6. All patients who have survived an episode of spontaneous bacterial peritonitis should receive long-term antibiotic prophylaxis.
7. The mainstay of therapy of hepatic encephalopathy involves therapy to lower blood ammonia concentrations and includes diet therapy, lactulose, and antibiotics alone or in combination with lactulose.

Chronic liver injury causes damage to normal liver tissue resulting in the development of regenerative nodules surrounded by fibrous bands.[1] Fibrosis, defined as the encapsulation or replacement of injured tissue by collagenous scar, results from an abnormal perpetuation of the normal wound healing process. If fibrotic liver disease advances, collagen bands progress to bridging fibrosis and eventually frank hepatic cirrhosis.[2] The word *cirrhosis* is derived from the Greek *kirrhos*, meaning orange-yellow, and refers to the color of the cirrhotic liver as seen upon autopsy or during surgery.[3] Cirrhosis is an advanced stage of liver fibrosis.[1] The advanced fibrosis of cirrhosis leads to shunting of the portal and arterial blood supply directly into hepatic outflow through the central veins, and exchange between hepatic sinusoids and hepatocytes is compromised. Clinical consequences of cirrhosis include impaired hepatocyte function, the increased intrahepatic resistance of portal hypertension, and hepatocellular carcinoma. Circulatory irregularities such as splanchnic vasodilation, vasoconstriction and hypoperfusion of the kidneys, water and salt retention, and increased cardiac output also occur.

1 While cirrhosis has many causes (Table 44–1), in the Western world, excessive alcohol intake and hepatitis C are the most common causes.[1,3,4] This chapter elucidates the pathophysiology of cirrhosis and the resultant effects on human anatomy and physiology. Treatment strategies for managing the most commonly encountered clinical complications of cirrhosis are discussed.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

EPIDEMIOLOGY

The exact prevalence of cirrhosis is unknown, but a reasonable estimate is that 1% of populations have histologically diagnosable cirrhosis.[1] Cirrhosis was responsible for over 28,000 deaths in America in 2007, and chronic liver disease continues to be ranked twelfth among the leading causes of death in the United States.[5] Acute variceal bleeding and spontaneous bacterial peritonitis are among the immediately life-threatening complications of cirrhosis. Associated conditions causing significant morbidity include ascites and hepatic encephalopathy. Approximately 50% of patients with cirrhosis develop ascites during 10 years of observation and, within 2 years, nearly half of patients who develop ascites will die.[6]

TABLE 44-1 Etiology of Cirrhosis

Chronic alcohol consumption
Chronic viral hepatitis (types B, C, and D)
Metabolic liver disease
Hemochromatosis
Wilson's disease
Alpha 1-antitrypsin deficiency
Nonalcoholic steatohepatitis ("fatty liver")
Cystic fibrosis
Immunologic disease
Autoimmune hepatitis
Primary biliary cirrhosis
Primary sclerosing cholangitis (90% associated with ulcerative colitis)
Vascular disease
Budd-Chiari
Cardiac failure
Drugs
Isoniazid, methyldopa, amiodarone, methotrexate, tamoxifen, retinol (vitamin A), propylthiouracil, didanosine

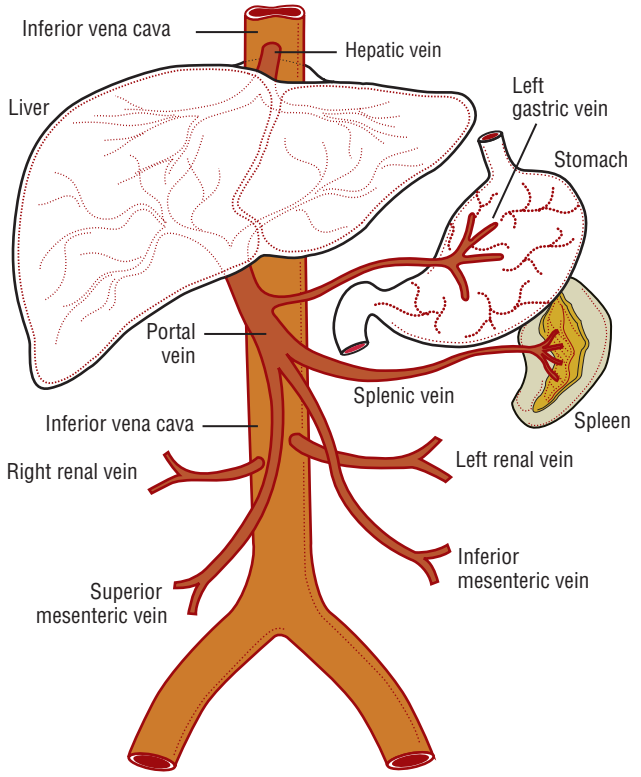

FIGURE 44-1. The portal venous system.

PATHOPHYSIOLOGY OF CIRRHOSIS

Any discussion of cirrhosis must be based on a firm understanding of hepatic anatomy and vascular supply. Conceptually, the liver can be thought of as an elaborate blood filtration system receiving blood from the hepatic artery and the portal vein (Fig. 44–1), with portal blood originating from the mesenteric, gastric, splenic, and pancreatic veins.[7] Blood enters the liver via the portal triad, which contains branches of the portal vein and hepatic artery, bile ducts, and lymphatic and nerve tissue. It then drains through the sinusoidal spaces (also known as the space of Disse) of the hepatic lobule (Fig. 44–2), which are lined by the workhorses of the liver, the hepatocytes. Individual hepatocytes are arranged in plates that are one cell thick. The six or more surfaces of each individual hepatocyte make contact with adjacent hepatocytes, border the bile canaliculi, or are exposed to the sinusoidal space. Filtered blood travels into the terminal hepatic venules, also called central veins, and then empties into larger hepatic veins and eventually into the inferior vena cava. Functional gradients of hepatocytes based on oxygen saturation have been reported. Hepatocytes closest to the portal triad, which contains the hepatic artery, have twice the oxygen saturation of those hepatocytes nearer to the terminal hepatic venule. Those hepatocytes closest to the portal triad also have higher levels of peroxisomes, glucose-6-phosphatase activity, urea cycle activity, bile acid uptake, glutathione content, and glycogen synthesis.

Normally, hepatic stellate cells function to store vitamin A and help to maintain the normal matrix in the sinusoidal space.[8] During chronic liver disease, however, hepatic stellate cells undergo an "activation" process, which is the central event in the development of hepatic fibrosis. Activation causes stellate cells to lose vitamin A, become highly proliferative, and synthesize fibrotic scar tissue, which accumulates in the sinusoidal space. This leads to loss of hepatocyte microvilli, loss of sinusoidal endothelial fenestrae, deterioration of hepatocyte function, and, if fibrosis progresses, eventual cirrhosis.

Cirrhosis causes changes to the splanchnic vascular bed as well as the systemic circulation.[9] Splanchnic vasodilation, decreased responsiveness to vasoconstrictors, and the formation of new blood vessels contribute to an increased splanchnic blood flow, formation of gastroesophageal varices, and variceal bleeding. All of these components are part of the portal hypertensive syndrome. Portal hypertension is characterized by hypervolemia, increased cardiac index, hypotension, and decreased systemic vascular resistance. This is a so-called hyperkinetic syndrome, which leads to a marked activation of neurohumoral vasoactive factors, a response that occurs in an effort to maintain the arterial blood pressure within normal limits. Activation of neurohumoral vasoactive factors is a main component in the pathophysiology of the ascites and renal dysfunction that often accompany chronic liver disease. Portal-systemic shunting may also occur and is involved in hepatic encephalopathy and other complications.

In summary, cirrhosis results from fibrotic changes within the hepatic sinusoids and results in changes in the levels of vasodilatory and vasoconstrictor mediators and an increase in blood flow to the splanchnic vasculature.

ANATOMIC AND PHYSIOLOGIC EFFECTS OF CIRRHOSIS

Cirrhosis and the pathophysiologic abnormalities that cause it result in the commonly encountered problems of ascites, portal hypertension, esophageal varices, hepatic encephalopathy, and coagulation disorders. Other less commonly seen problems in patients with cirrhosis include hepatorenal syndrome, hepatopulmonary syndrome, and endocrine dysfunction. These are discussed in the section dealing with the management of cirrhotic complications.

ASCITES

Ascites is the accumulation of an excessive amount of fluid within the peritoneal cavity.[10] It is the most commonly occurring major complication of cirrhosis.[6] Approximately half of all cirrhotic patients develop ascites within 10 years of diagnosis. Several hypotheses have been offered to explain the mechanism for the development of ascites in decompensated cirrhosis.[10] Most acceptable theories state that ascites formation begins as a result of the development of sinusoidal hypertension and portal hypertension. Portal hypertension activates vasodilatory mechanisms that are mediated mostly by nitric oxide overproduction. This leads to splanchnic and peripheral arteriolar vasodilation and, in advanced disease, a drop in arterial pressure. Baroreceptor-mediated activation of the renin-angiotensin-aldosterone system, activation of the sympathetic nervous system, and release of antidiuretic hormone occur in response to the resulting arterial hypotension in an effort to restore normal blood pressure (Fig. 44–3). These changes cause renal sodium and water retention. Additionally, ongoing splanchnic vasodilation increases splanchnic lymph production beyond the capacity of the lymph transportation system. Leakage of lymphatic fluid into the peritoneal cavity occurs. Persistent renal sodium and water retention, increased splanchnic vascular permeability, and lymph leakage into the peritoneal cavity combine to create the sustained ascites formation of end-stage liver disease.

PORTAL HYPERTENSION AND VARICES

Sinusoidal portal hypertension is most often caused by alcohol-induced cirrhosis.[11] It is associated with acute variceal bleeding, a medical emergency that carries a mortality rate of 20% at 6 weeks and is among the most severe complications of cirrhosis.[12] Portal

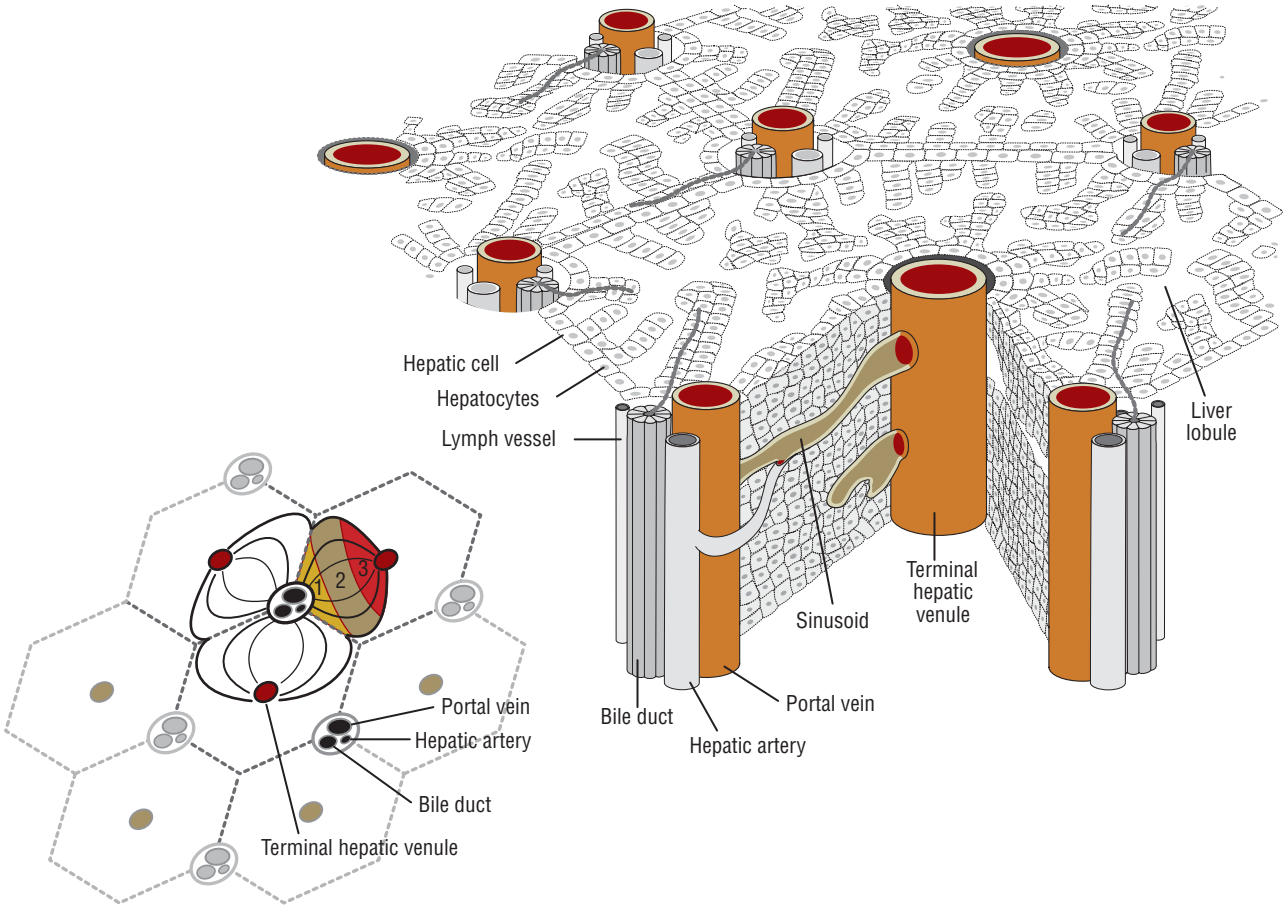

FIGURE 44-2. The hepatic lobule.

hypertension is defined by the presence of a gradient of greater than 5 mmHg between the portal and central venous pressures (see Fig. 44–1).[11] The gradient is called the hepatic venous pressure gradient (HVPG). Esophageal and gastric varices arise after the pressure gradient of 8 to 10 mm Hg is reached, and bleeding can occur from these varices once the gradient rises above 12 mmHg. Varices occur because of the body's need to find collateral outlets to relieve the increased pressure of portal hypertension. Other outlets, besides esophageal and gastric varices, include retroperitoneal vessels, the hemorrhoidal venous plexus, a recanalized umbilical vein, and intrahepatic shunts. Five percent of patients with cirrhosis are expected to develop varices within 1 year, and 28% will develop them within 3 years. Acute variceal bleeding occurs in 25% to 40% of cirrhosis patients and is the cause of death for one third of these patients.

Progression to bleeding can be predicted by Child-Pugh score, red wale markings on the varices, and an alcoholic etiology of liver disease. Twelve percent of patients with small varices at initial endoscopy will experience variceal bleeding within 2 years. Twenty to 29% of patients with variceal bleeding will die within 30 days. Rebleeding is common following initial hemorrhage, especially within the first 72 hours. More than 50% of recurrent bleeding episodes occur within the first 10 days of the initial bleed, and risk returns to baseline after 6 weeks. Primary prevention of bleeding is a major goal in the therapy of portal hypertension, and strategies include both pharmacologic and surgical approaches.

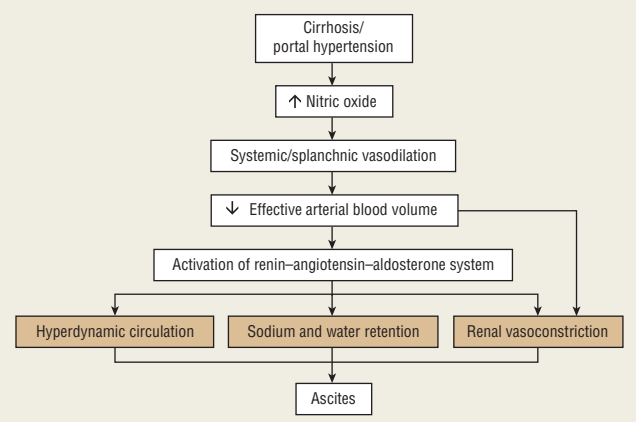

FIGURE 44-3. Pathogenesis of ascites.

HEPATIC ENCEPHALOPATHY

The term *hepatic encephalopathy* (HE) describes a wide range of neuropsychiatric symptoms that are associated with liver failure.[13] Symptoms of HE are thought to result from an accumulation of gut-derived nitrogenous substances in the systemic circulation as a consequence of decreased hepatic functioning and shunting through portosystemic collaterals bypassing the liver.[14] Once these substances enter the central nervous system, they cause alterations of neurotransmission that affect consciousness and behavior. Ammonia is the most commonly cited culprit in the pathogenesis of HE, but glutamate, benzodiazepine receptor agonists, and manganese are also potential causes.[13,14] Arterial ammonia levels are increased commonly in both acute and chronic liver disease, but an established correlation between blood ammonia levels and mental

status does not exist.[14] Despite this, interventions to lower blood ammonia levels remain the mainstay of treatment for HE.

HE is now categorized as type A, B, or C based on nomenclature developed by the 11th World Congress of Gastroenterology.[13] Type A is HE induced by acute liver failure, Type B is due to portal-systemic bypass without associated intrinsic liver disease, and type C is HE that occurs in patients with cirrhosis. The duration and characteristics of HE are classified as episodic, persistent, and minimal. Episodic HE occurs spontaneously or is precipitated by a clinical factor, such as gastrointestinal bleeding. Recurrent HE is defined by two episodes of spontaneous or precipitated HE occurring within 1 year, and the hallmark of persistent HE is chronic cognitive deficits that decrease a patient's quality of life. Minimal HE refers to cirrhotic patients who do not suffer clinically overt cognitive dysfunction but who are found to have cognitive impairment on psychological studies. The onset of HE in a patient with liver failure may be related to the presence of several known precipitating factors. In cases of HE associated with a precipitant, if that precipitant can be cured or discontinued, it may also be possible to discontinue treatment for HE. In many cases, no precipitant is found and, therefore, long-term treatment of HE may be required.

COAGULATION DEFECTS

The liver synthesizes most of the proteins that are responsible for the maintenance of hemostasis (the balance between coagulation and anticoagulation).[15] Hepatocellular damage can lead to a disruption in hemostasis because of defects it may cause in the function of coagulation and fibrinolytic factors. These defects include a reduction in the synthesis of clotting factors, excessive fibrinolysis, disseminated intravascular coagulation, thrombocytopenia, and platelet dysfunction. Most coagulation factors are created in the liver, and the levels of these factors can be significantly reduced in chronic liver disease associated with extensive hepatocellular damage. Factor VII is the first factor to decrease as liver function declines due to its short half-life. A reduction in clotting factor VII is common in end-stage liver disease, affecting 60% of patients. Low factor VII activity is prognostic for reduced survival, and the prothrombin time is a standard component of the Child-Pugh scoring system. Accelerated intravascular coagulation and fibrinolysis can be detected in some patients with cirrhosis. The coexistence of sepsis, shock, surgery, trauma, or ascites may cause a progression from accelerated intravascular coagulation to disseminated intravascular coagulation. In patients with cirrhosis, disseminated intravascular coagulation involves increased release of procoagulants, impaired removal of activated coagulation factors and endotoxins produced by gut bacteria, and reduced synthesis of coagulation inhibitors. Both platelet number and function may also be affected in cirrhosis. Platelet numbers are reduced by multiple mechanisms, including splenomegaly due to portal hypertension and sequestration of platelets in the spleen, reduced hepatic production of thrombopoietin, bone marrow suppression, and increased platelet destruction. Mild to moderate thrombocytopenia occurs in 15% to 70% of patients with cirrhosis. The net effect of the coagulation disorders that occur in cirrhosis is the development of bleeding.

CLINICAL PRESENTATION

Cirrhotic patients may present in a variety of ways, from asymptomatic with abnormal radiographic or laboratory studies to decompensated with ascites, spontaneous bacterial peritonitis, hepatic encephalopathy, or variceal bleeding.[16]

CLINICAL PRESENTATION OF CIRRHOSIS

Signs and Symptoms

- Asymptomatic
- Hepatomegaly, splenomegaly
- Pruritis, jaundice, palmar erythema, spider angiomata, hyperpigmentation
- Gynecomastia, reduced libido
- Ascites, edema, pleural effusion, and respiratory difficulties
- Malaise, anorexia, and weight loss
- Encephalopathy

Laboratory Tests

- Hypoalbuminemia
- Elevated prothrombin time
- Thrombocytopenia
- Elevated alkaline phosphatase
- Elevated aspartate transaminase (AST), alanine transaminase (ALT), and γ-glutamyl transpeptidase (GGT)

The approach to a patient with suspected liver disease begins with a thorough history and physical exam. Some presenting characteristics of patients with cirrhosis include anorexia, weight loss, weakness, fatigue, jaundice, pruritis, gastrointestinal bleeding, coagulopathy, increasing abdominal girth with shifting flank dullness, mental status changes, and vascular spiders. Osteoporosis, as a result of vitamin D malabsorption and resultant calcium deficiency, can also occur.

A thorough history including risk factors that predispose patients to cirrhosis should be taken.[16] Quantity and duration of alcohol intake should be determined. Risk factors for hepatitis B and C transmission should be inquired about. These include birthplace in endemic areas, sexual history, intranasal or intravenous drug use, body piercing or tattooing, and accidental contamination of body tissues or blood. Information concerning any history of transfusions, as well as any personal history of autoimmune or hepatic diseases, should be gathered. A family history should also be taken, looking especially for any family member with a prior history of autoimmune or hepatic diseases.

LABORATORY ABNORMALITIES

There are no laboratory or radiographic tests of hepatic function that can accurately diagnose cirrhosis.[16] Despite this, liver function tests, a complete blood count with platelets, and a prothrombin time test should be performed if liver disease is suspected. Tests that measure the level of serum liver enzymes are usually referred to as liver function tests.[17] However; these tests actually reflect hepatocyte integrity or cholestasis, not liver function.

Routine liver tests include alkaline phosphatase, bilirubin, aspartate transaminase (AST), alanine transaminase (ALT), and γ-glutamyl transpeptidase (GGT). Additional markers of hepatic synthetic activity include albumin and prothrombin time. Liver function tests are often the first step in the evaluation of patients who present with symptoms or signs suggestive of cirrhosis.[16] The use of liver function tests in the diagnosis and management of cirrhosis is discussed in the following sections. It may be useful to group the tests into two broad categories: markers of hepatocyte integrity such as the transaminases and markers of liver function mass such as prothrombin time and albumin.[17]

Aminotransferases

The aminotransferases, AST and ALT, are enzymes that are highly concentrated in the liver. Liver injury, whether acute or chronic,

results, at some point in the course of the disease, in increases in the serum concentrations of the aminotransferase enzymes. The degree of elevation, rate of rise, and nature of the course of alteration in aminotransferase serum levels are helpful in suggesting possible etiologies. Liver function tests will typically be elevated to the highest levels in acute viral, ischemic, or toxic liver injury. Chronic hepatitis and cirrhosis patients may present with elevated aminotransferase levels, but they may also present with aminotransferase levels within the normal reference range. The degree of aminotransferase level elevation is dependent upon the course of the hepatic injury being experienced by the patients and also depends on when the enzyme levels are tested. In a landmark study by Cohen and Kaplan, alcoholic liver disease resulted in AST elevations of only six to seven times the upper limit of normal in 98% of patients.[18] The ratio of AST to ALT also provides information in patients with suspected alcoholic liver disease. Seventy percent of patients with alcoholic liver disease in the study by Cohen and Kaplan had ratios greater than two, whereas 92% of patients had ratios greater than one.

Alkaline Phosphatase and Gamma-Glutamyl Transpeptidase

Elevated serum levels of alkaline phosphatase and GGT occur in cases of liver injury with a cholestatic pattern and therefore accompany conditions such as primary biliary cirrhosis, primary sclerosing cholangitis, drug-induced cholestasis, bile duct obstruction, autoimmune cholestatic liver disease, and metastatic cancer of the liver.[17] Neither alkaline phosphatase nor GGT is found solely in the liver, and elevations in either of these biomarkers can occur in a variety of disease states affecting other bodily tissues. However, the combination of an elevation in alkaline phosphatase level with a concomitant elevation in GGT level increases clinical suspicion of hepatic etiology.

Child-Pugh Classification and Model for End-Stage Liver Disease Score

The Child-Pugh classification system has gained widespread acceptance as a means of quantifying the myriad effects of the cirrhotic process on the laboratory and clinical manifestations of this disease.[19] Recommended drug dosing adjustments for patients in liver failure, when available, are normally based upon the Child-Pugh score. The newer Model for End-stage Liver Disease (MELD) scoring system is now the accepted classification scheme used by the United Network for Organ Sharing (UNOS) in the allocation livers for transplantation.[20] The Child-Pugh classification system employs a combination of physical and laboratory findings (Table 44–2), whereas the MELD score calculation takes into account a patient's serum creatinine, bilirubin, international normalized ratio (INR), and etiology of liver disease omitting the more subjective reports of ascites and encephalopathy used

TABLE 44-2 Criteria and Scoring for the Child-Pugh Grading of Chronic Liver Disease

Score	1	2	3
Total bilirubin (mg/dL)	1–2	2–3	>3
Albumin (g/dL)	>3.5	2.8–3.5	<2.8
Ascites	None	Mild	Moderate
Encephalopathy (grade)	None	1 and 2	3 and 4
Prothrombin time (seconds prolonged)	1–4	4–6	>6

Grade A, <7 points; grade B, 7–9 points; grade C, 10–15 points.
Data from reference 19.

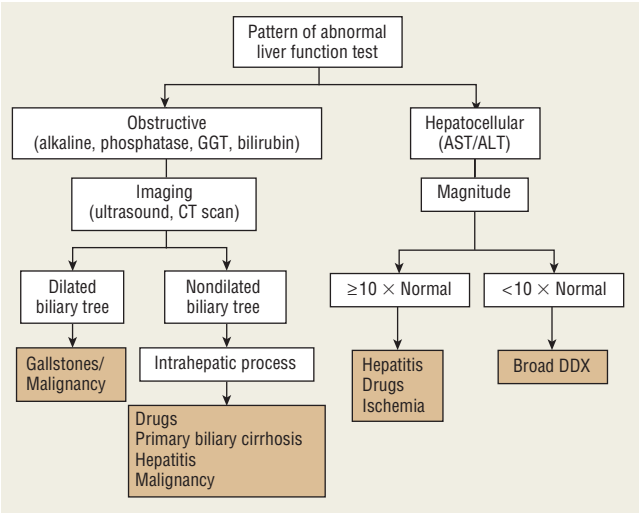

FIGURE 44-4. Interpretation of liver function tests. DDX; differential diagnosis.

in the Child-Pugh system. The MELD scoring calculation is as follows:[21]

$$\text{MELD score} = 0.957 \times \text{Log}_e(\text{creatinine mg/dL}) + 0.378 \times \text{Log}_e(\text{bilirubin mg/dL}) + 1.120 \times \text{Log}_e(\text{INR}) + 0.643^*$$

These classification systems are important because they are used to assess and define the severity of the cirrhosis, and as a predictor for patient survival, surgical outcome, and risk of variceal bleeding.

Bilirubin

Bilirubin is the product of the breakdown of hemoglobin molecules in the reticuloendothelial system.[17] Elevations in serum conjugated bilirubin indicate that the liver has lost at least half of its excretory capacity and are usually a sign of liver disease. When found in conjunction with markedly elevated AST and ALT, conjugated hyperbilirubinemia indicates the possible presence of acute viral hepatitis, autoimmune hepatitis, toxic liver injury, or ischemic liver injury. Elevated conjugated bilirubin levels with concomitant increases in alkaline phosphatase and normal aminotransferase levels are a sign of cholestatic disease and possible cholestatic drug reactions. Causes of elevations in unconjugated bilirubin include hemolysis, Gilbert syndrome, hematoma reabsorption, and ineffective erythropoiesis. Causes of conjugated hyperbilirubinemia include bile duct obstruction, hepatitis, cirrhosis, primary sclerosing cholangitis, primary biliary cirrhosis, total parenteral nutrition, drug toxins, and vanishing bile duct syndrome. When cirrhosis has been established, the degree of bilirubin elevation has prognostic significance and is used as a component of the Child-Pugh and MELD scoring systems for quantifying the degree of cirrhosis.[19,21]

Figure 44–4 describes a general algorithm for the interpretation of liver function tests. The algorithm first separates the tests into two categories based on the underlying pathology (pattern of elevations): obstructive (alkaline phosphatase, GGT, and bilirubin) versus hepatocellular (AST and ALT). If a hepatocellular pattern predominates, the magnitude of elevation provides diagnostic assistance. If the degree of elevation is greater than

*Multiply the score by 10 and round to the nearest whole number. (Laboratory values less than 1 are rounded up to 1 for the purposes of the MELD calculation.)

10 times normal, the etiology is likely a result of drugs or other toxins, ischemia, or acute viral hepatitis. Elevations less than 10 times normal have a broad differential. Unfortunately, most liver enzyme abnormalities will fall into a mixed pattern providing limited diagnostic assistance.

Albumin and Coagulation Factors

Albumin and coagulation proteins are markers of hepatic synthetic activity and are therefore used to estimate the level of hepatic functioning in cirrhosis.[17] Albumin and prothrombin time (PT) are used in the Child-Pugh system for quantifying liver disease, and the INR is used in the MELD scoring system as a marker of coagulation.[19,21] Albumin levels can be affected by a number of factors, including malnutrition, malabsorption, and protein losses from renal and intestinal sources.[17]

Coagulation factors I, II, V, VII, VIII, IX, X, XI, XII, and XIII are synthesized in the liver, and significantly reduced levels of coagulation factors II, V, VII, and XIII have been observed in patients with chronic liver disease and systemic bleeding unrelated to portal hypertension.[15] PT prolongation has also been observed in patients with chronic liver disease also have PT prolongation. The PT has been used in cases of acetaminophen-induced hepatic failure, viral hepatitis, and drug reactions as a prognostic laboratory value.[22] A PT over 100 seconds correlates with poor prognosis in acetaminophen-induced hepatic failure, and over 50 seconds indicates a poor prognosis in cases of viral hepatitis and drug reactions.

Thrombocytopenia

Thrombocytopenia (generally defined as a platelet count less than 150,000) is a common feature of chronic liver disease found in 15% to 70% of cirrhotic patients depending on the stage of liver disease and definition of thrombocytopenia.[15] The etiology of thrombocytopenia in liver disease is multifactorial, involving primarily splenomegaly due to portal hypertension with pooling of platelets in the spleen. A decrease in thrombopoietin due to decreased hepatic synthesis occurs as well as an immune-mediated destruction of platelets. Additionally, bone marrow suppression related to the hepatitis C virus or interferon antiviral treatment may exist and lead to thrombocytopenia associated with the cirrhotic process.

ENDOSCOPIC AND RADIOGRAPHIC ABNORMALITIES

While no radiographic test is considered a diagnostic standard for cirrhosis, radiographic studies may be used to detect ascites, hepatosplenomegaly, hepatic or portal vein thromboses, and hepatocellular carcinoma.[16] Ultrasonography, because it does not require radiation exposure or intravenous contrast and is relatively low cost, should be the first radiographic study in the evaluation of a patient with suspected cirrhosis. Hepatic nodularity, irregularity, increased echogenicity, and atrophy are all ultrasonographic findings indicative of cirrhosis. Ascites may also be detected on ultrasound. Computed tomography and magnetic resonance imaging can demonstrate liver nodularity as well as atrophic and hypertrophic changes. Ascites and varices may also be detected on computed tomography or magnetic resonance imaging scans. Portal vein patency can be assessed by computer tomography imaging.

LIVER BIOPSY

Liver biopsy should be considered after a thorough noninvasive workup has failed to confirm a diagnosis in suspected cirrhosis. Liver biopsy has a sensitivity and specificity of 80% to 100% for an accurate diagnosis of cirrhosis and its etiology. The success of biopsy as a diagnostic tool is dependent upon the number of histologic samples retrieved as well as the sampling method used.

TREATMENT

Cirrhosis

GENERAL APPROACHES TO TREATMENT

General approaches to therapy in cirrhosis should include the following:

1. Identify and eliminate, where possible, the causes of cirrhosis (e.g., alcohol abuse).
2. Assess the risk for variceal bleeding and begin pharmacologic prophylaxis when indicated. Prophylactic endoscopic therapy can be used for patients with high-risk medium and large varices as well as in patients with contraindications or intolerance to nonselective β-adrenergic blockers. Endoscopic therapy is also appropriate for patients suffering acute bleeding episodes. Variceal obliteration with endoscopic techniques in conjunction with pharmacological intervention is the recommended treatment of choice in patients with acute bleeding.
3. Evaluate the patient for clinical signs of ascites and manage with pharmacologic therapy (e.g., diuretics) and paracentesis. Careful monitoring for spontaneous bacterial peritonitis (SBP) should be used in patients with ascites who undergo acute deterioration.
4. Hepatic encephalopathy is a common complication of cirrhosis and requires clinical vigilance and treatment with dietary restriction, elimination of central nervous system depressants, and therapy to lower ammonia levels.
5. Frequent monitoring for signs of hepatorenal syndrome, pulmonary insufficiency, and endocrine dysfunction is necessary.

DESIRED OUTCOMES

The desired therapeutic outcomes can be viewed in two categories: *resolution of acute complications* such as tamponade of bleeding and resolution of hemodynamic instability for an episode of acute variceal hemorrhage and *prevention of complications* through lowering of portal pressure with medical therapy using β-adrenergic blocker therapy or supporting abstinence from alcohol. Treatment end points and desired therapeutic outcomes are presented for each of the recommended therapies discussed.

MANAGEMENT OF PORTAL HYPERTENSION AND VARICEAL BLEEDING

The management of varices involves three strategies: (a) primary prophylaxis (prevention of the first bleeding episode); (b) treatment of acute variceal hemorrhage; and (c) secondary prophylaxis (prevention of rebleeding in patients who have previously bled).[12]

Primary Prophylaxis

***β*-Adrenergic Blockade** The mainstay of primary prophylaxis is the use of nonselective β-adrenergic blocking agents such as propranolol or nadolol.[11] These agents reduce portal pressure by reducing portal venous inflow via two mechanisms: a decrease in cardiac output through β_1-adrenergic blockade and a decrease in splanchnic blood flow through β_2-adrenergic blockade.[23]

Meta-analysis of 12 trials of the nonselective β-adrenergic blockers propranolol or nadolol demonstrated the effectiveness of these agents in the prevention of bleeding, especially in patients with medium- or large-sized varices, over a median follow-up of 2 years with a trend toward a reduction in mortality.[24] This analysis indicated that one bleeding episode is avoided for every 10 patients treated with a nonselective β-adrenergic blocker. Mortality was lowered in cirrhotic patients with esophageal varices who have never bled when those patients are treated with a β-adrenergic blocker.[25] In this analysis, it was found that one life was saved for every 17 patients treated with a β-adrenergic blocker. Nadolol reduces the rate of growth of small esophageal varices in patients with cirrhosis.[26] However, β-adrenergic blocker therapy does not prevent the formation of first varices.[23] Screening esophagogastroduodenoscopy (EGD) is recommended for the diagnosis of esophageal and gastric varices when the diagnosis of cirrhosis is made, repeated every 2 to 3 years in patients who have no varices upon initial surveillance, or repeated annually in the event of decompensation.[27,28] Once started, β-adrenergic blocker therapy should be continued for life unless it is not tolerated.[29]

Treatment Recommendations: Variceal Bleeding—Primary Prophylaxis

2 All patients with cirrhosis should be screened for varices upon diagnosis.[28] For patients with small varices (less than 5 mm) who have not bled and who have no criteria for increased risk of bleeding (increased risk includes those with Child-Pugh score of B or C or the presence of red wale marks on varices), β-adrenergic blocker therapy may be instituted, although long-term benefit has not been established. Patients with small varices plus risk factors for variceal hemorrhage should receive prophylaxis therapy with a nonselective β-adrenergic blocker (such as propranolol). All patients found to have medium to large varices (varices greater than 5 mm) that have not bled but have high risk for hemorrhage should receive prophylaxis therapy with a nonselective β-adrenergic blocker or endoscopic variceal ligation (EVL). Patients with medium and large varices who have not bled and who are at lower risk for hemorrhage should receive prophylaxis with nonselective β-adrenergic blocker therapy instead of EVL; although, EVL may be used in patients who are intolerant or nonadherent or who have contraindications to β-blocker therapy. Initiate therapy with oral propranolol 20 mg twice daily or nadolol 40 mg once daily and titrate to maximal tolerated dose. In most studies, the dose of nonselective β-adrenergic blocker was titrated to decrease the heart rate by 25% of baseline. Heart rate does not correlate with reduction in HVPG, and direct HVPG measurement is not widely available; therefore, titration of β-blocker therapy to the maximal tolerated dose is now recommended.[28,30]

Patients with contraindications to therapy with nonselective β-adrenergic blockers (i.e., those with asthma, insulin-dependent diabetes with episodes of hypoglycemia, and peripheral vascular disease) or intolerance to β-adrenergic blockers should be considered for alternative prophylactic therapy with EVL.[28] EVL has been compared to nonselective β-adrenergic blocker therapy in patients with large varices and found to be associated with a significantly lower incidence of first variceal bleed.[31,32] EVL is equivalent to nadolol and propranolol for prevention of first variceal bleed.[33–35] Current guidelines place EVL as a possible first option for primary prophylaxis in patients with high-risk medium to large varices.[28] EVL is the recommended secondary option for patients with lower-risk medium to large varices who are intolerant to, are nonadherent to, or have contraindications to nonselective β-adrenergic blocker therapy. Nitrates are no longer recommended as alternative therapy for primary prophylaxis against variceal bleeding in patients with intolerance to nonselective β-adrenergic blockers.[28] In fact, isosorbide mononitrate was found in one study to result in a greater 1- and 2-year probability of first variceal bleed with no difference in survival as compared to placebo.[36] At this time, there is also insufficient evidence to support the use of other therapies and procedures (such as combination nonselective β-adrenergic blocker therapy with isosorbide mononitrate, combination nonselective β-adrenergic blocker therapy with spironolactone, combination nonselective β-adrenergic blocker therapy with EVL, shunt surgery, and endoscopic sclerotherapy) for primary prevention of variceal hemorrhage.[28] Nonselective β-adrenergic blocker therapy remains the mainstay of therapy in portal hypertension patients with known varices to avoid first variceal bleeding.

ACUTE VARICEAL HEMORRHAGE

Variceal hemorrhage is a medical emergency that carries a mortality rate of 15% to 20%, requires admission to an intensive care unit, and is one of the most feared complications of cirrhosis.[28,37] It is important to note that variceal bleeding secondary to portal hypertension can occur in patients without signs of liver disease; for example, in patients with chronic portal vein thrombosis.[38] Treatment of acute variceal bleeding includes general stabilizing and assessment measures as well as specific measures to control the acute hemorrhage and prevent early recurrence.[28,37]

Management of Acute Variceal Hemorrhage

Initial treatment goals include (a) adequate blood volume resuscitation, (b) protection of airway from aspiration of blood, (c) correction of significant coagulopathy and/or thrombocytopenia with fresh frozen plasma and platelets, (d) prophylaxis against SBP and other infections, (e) control of bleeding, (f) prevention of rebleeding, and (g) preservation of liver function.[28] Prompt stabilization of blood volume with a goal of maintaining hemodynamic stability and a hemoglobin of 8 g/dL should be undertaken. Volume should be expanded to maintain a systolic blood pressure of 90 to 100 mm Hg and a heart rate of less than 100 beats per minute, but vigorous resuscitation with saline solution should generally be avoided because this may lead to recurrent variceal hemorrhage or accumulation of ascites and/or fluid at other anatomical sites.[28,37] Use of recombinant factor VIIa therapy is not recommended in cirrhotic patients with GI hemorrhage at this time. Airway management is critical in patients with variceal hemorrhage, especially those with concomitant hepatic encephalopathy or severe bleeding.[28] Elective or more emergent intubation may be required prior to diagnostic endoscopy. Combination pharmacological therapy plus endoscopic therapy with preferably EVL, or sclerotherapy if EVL is not technically feasible, is considered the most rational approach to the treatment of acute variceal bleeding.[12,28]

Vasoactive drug therapy (usually octreotide) is routinely used early to stop or slow bleeding for patient management as soon as a diagnosis of variceal bleeding is suspected, and potentially even before EGD. Antibiotic therapy to prevent SBP and other infections, as well as to prevent rebleeding and decrease mortality, should be implemented. Figure 44–5 presents an algorithm for the management of variceal hemorrhage.

Drug Therapy

Drugs employed to manage acute variceal bleeding in the United States include (a) the somatostatin analogue octreotide and (b) vasopressin. These agents work as splanchnic vasoconstrictors, thus decreasing portal blood flow and pressure. Agents available

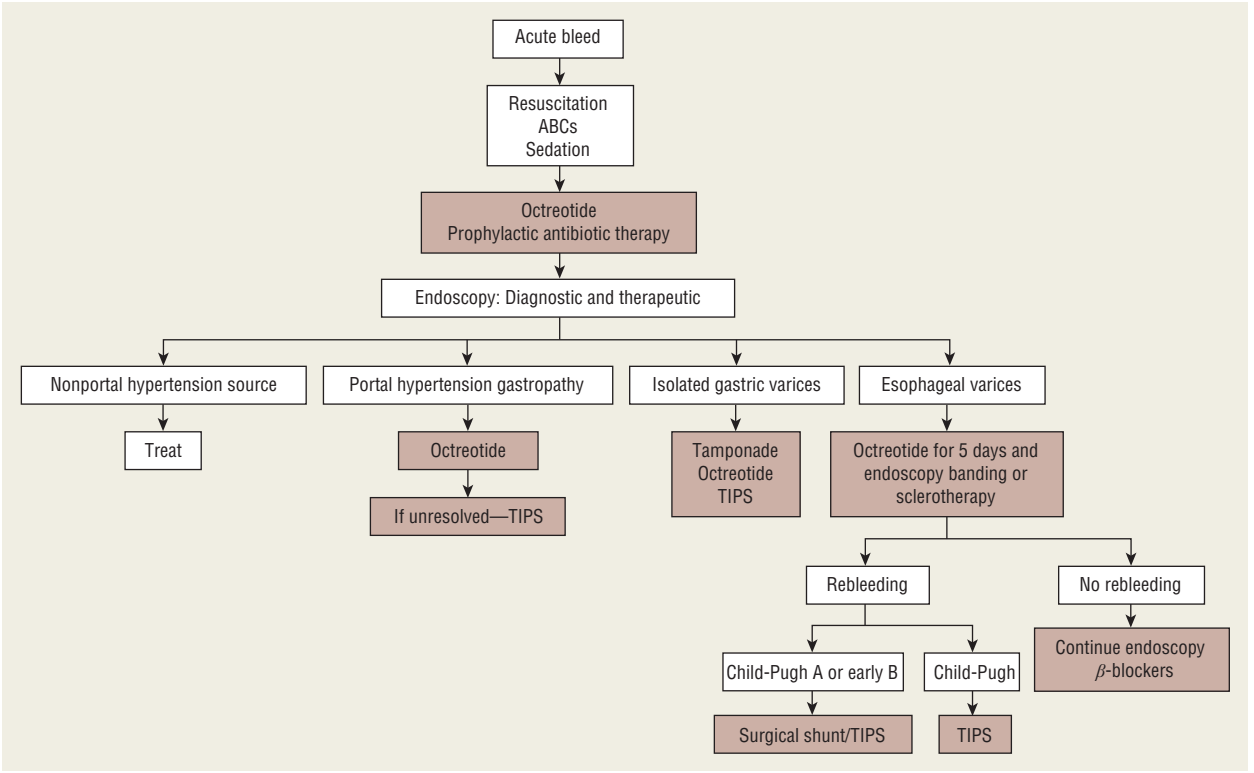

FIGURE 44-5. Management of acute variceal hemorrhage.

in other countries also include terlipressin, which is an analogue of vasopressin, and another somatostatin analogue, vapreotide.

Somatostatin and Octreotide Somatostatin is a naturally occurring tetradecapeptide hormone, and octreotide is a synthetic octapeptide that shares a four–amino acid segment with somatostatin and has similar pharmacologic activity with greater potency and longer duration of action as compared with somatostatin.[39] Somatostatin and octreotide cause a reduction in portal pressure and port-collateral blood flow through inducing splanchnic vasoconstriction without causing the systemic effects associated with vasopressin.[28,39] The splanchnic vasoconstriction found with somatostatin and octreotide therapy is due to inhibition of the release of vasodilatory peptides like glucagon; however, octreotide has a local vasoconstrictive effect confined to the splanchnic vasculature.[28] Somatostatin and somatostatin analogues are associated with fewer side effects as compared with vasopressin.[24] Octreotide is available as both subcutaneous and intravenous injection, though the most recent recommended dosing of octreotide for variceal bleeding consists of an initial intravenous bolus of 50 mcg followed by a continuous intravenous infusion of 50 mcg per hour.[28,37] Because octreotide is safe for continuation for multiple days and because around half of early recurrent bleeding occurs within in the first 3 to 5 days, guidelines suggest continuation of octreotide for 5 days after acute variceal bleeding.[28,37,40] Studies have been conducted comparing octreotide with placebo, with balloon tamponade, with vasopressin, and with glypressin for the treatment of acute variceal bleeding with somewhat mixed results.[41–46] While studies comparing octreotide with placebo or with balloon tamponade did not find octreotide to be superior for controlling bleeding, octreotide was significantly better for survival as compared with balloon tamponade.[41,42] No significant differences in bleeding control or mortality were found in studies comparing octreotide with vasopressin or terlipressin.[43–46] A meta-analysis of studies of somatostatin analogues in general also failed to showed a beneficial effect.[47] A meta-analysis comparing either endoscopic therapy (with sclerotherapy or EVL) alone or endoscopic therapy plus octreotide, somatostatin, or vapreotide showed improved initial control of bleeding and 5-day hemostasis with combination therapy without any differences in mortality or severe adverse events.[48] Octreotide used alone may be less effective for controlling bleeding due to tachyphylaxis and a more transient effect relative to terlipressin.[49,50]

Vasopressin (also known as antidiuretic hormone) is a potent, nonselective vasoconstrictor that reduces portal pressure by causing splanchnic vasoconstriction, which reduces splanchnic blood flow.[39] Unfortunately, the vasoconstrictive effects of vasopressin are nonselective—the vasoconstriction is not restricted to the splanchnic vascular bed. Potent systemic vasoconstriction induces peripheral resistance, which reduces cardiac output, heart rate, and coronary blood flow. These effects on cardiac hemodynamics can lead to myocardial ischemia or infarction, arrhythmias, mesenteric ischemia, ischemia of the limbs, and cerebrovascular accidents. A meta-analysis of four randomized, controlled clinical trials of vasopressin for variceal hemorrhage demonstrated that vasopressin was significantly more effective than no treatment at controlling bleeding; however, mortality was not affected.[24] Adverse effects were reported in one to two thirds of patients, and vasopressin was discontinued in about 25% of patients secondary to adverse effects. A meta-analysis comparing vasopressin and somatostatin in the management of acute esophageal variceal hemorrhage found somatostatin more efficacious for controlling acute hemorrhage from esophageal varices with significantly less adverse effects.[51] Only four patients must be treated with somatostatin over vasopressin for one to derive additional benefit in terms of initial control of bleeding, and only nine patients need to be treated with somatostatin instead of vasopressin in order for one to experience benefit in terms of avoidance of rebleeding. Though somatostatin is not available in the United States today, its

analogue octreotide is commonly used instead of vasopressin for acute variceal hemorrhage.

A recommended dosing strategy for vasopressin is a continuous intravenous infusion of 0.2 to 0.4 units per minute, which can be increased to a maximal dose of 0.8 units per minute.[28] Vasopressin should only be used at the highest effective dose continuously for a maximum of 24 hours and should always be administered with intravenous nitroglycerin at a starting dose of 40 mcg per minute (which can be increased to a maximum of 400 mcg per minute and adjusted to maintain systolic blood pressure over 90 mm Hg) in order to minimize the risk of serious adverse events. With the recent addition of safer and equally effective treatment alternatives, vasopressin, alone or combined with nitroglycerin, can no longer be recommended as first-line therapy for the management of variceal hemorrhage.[28] Terlipressin, a synthetic analogue of vasopressin, has fewer side effects and a longer duration of action than vasopressin. It reduces mortality in acute variceal hemorrhage but is not currently available in the United States.[24]

Cirrhotic patients with active bleeding are at high risk of severe bacterial infections such as SBP.[28] Short-term prophylactic antibiotic therapy to reduce the risk of infection during episodes of bleeding not only reduces the likelihood of development of SBP and other infections, it also reduces the incidence of rebleeding and increases short-term survival.[52–54] Prophylactic antibiotic therapy should be prescribed for all patients with cirrhosis and acute variceal bleeding.[28] A short course (7 days maximum) of oral norfloxacin 400 mg twice daily or intravenous ciprofloxacin when the oral route is not available is recommended. Alternatively, in patients with severe cirrhosis in areas with high quinolone resistance, intravenous ceftriaxone 1 g per day may be preferable.

Endoscopic Interventions: Sclerotherapy and Band Ligation

The Baveno IV Consensus Report recommended that endoscopy be performed as soon as possible following admission in cases of suspected variceal hemorrhage, especially in cases of significant bleeding and in patients with suspected cirrhosis.[12] Endoscopy is used to diagnose variceal bleeding, and endoscopic techniques, such as EVL and sclerotherapy, can be used in an attempt to stop variceal bleeding. EVL consists of placement of rubber bands around the varix through a clear plastic channel attached to the end of the endoscope. After the rubber bands are in place, the varix will slough off after 48 to 72 hours. Typically, the EVL procedure is repeated every 1 to 2 weeks until variceal obliteration is attained. Surveillance endoscopy is then performed 1 to 3 months after obliteration and then repeated every 6 to 12 months indefinitely.[28,37] Endoscopic sclerotherapy involves injection of 1 to 4 mL of a sclerosing agent into the lumen of the varices to tamponade blood flow. EVL is more effective than sclerotherapy with greater control of hemorrhage, less risk for rebleeding, and lower likelihood of adverse events.[32,55] No difference in mortality has been found between these two endoscopic procedures; however. HVPG is increased following both EVL and sclerotherapy, though HVPG decreases to baseline within 2 days following EVL and remains elevated for longer following sclerotherapy.[56] Consensus recommendation calls for EVL (in conjunction with pharmacological therapy) as the recommended form of endoscopic therapy for acute variceal bleeding, though endoscopic sclerotherapy may be employed if ligation is technically difficult.[12]

Endoscopic injection of the tissue adhesive N-butyl-cyanoacrylate to control acute gastric variceal bleeding as well as EVL was associated with a lower rate of rebleeding as compared with EVL in one trial.[57] Endoscopic therapy with 2-octyl cyanoacrylate is effective for initial control of bleeding from fundal varices as well as prevention of rebleeding.[58] Therefore, endoscopic therapy with these agents is recommended for patients with acute bleeding from gastric varices.[12,28]

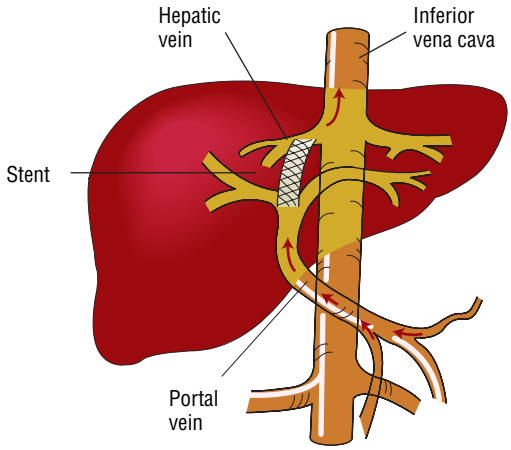

FIGURE 44-6. Transjugular intrahepatic portosystemic shunt (TIPS).

Interventional and Surgical Treatment Approaches

Standard therapy fails to control initial bleeding or early rebleeding in 10% to 20% of patients with acute variceal hemorrhage.[37] In these cases, a salvage procedure, such as balloon tamponade or transjugular intrahepatic portosystemic shunt (TIPS), is necessary. Balloon tamponade is effective in controlling variceal bleeding temporarily; however, rebleeding is common after balloon deflation, and complications result in mortality rates of up to 20% with balloon tamponade.[37] Sengstaken-Blakemore tubes are recommended for used in esophageal variceal bleeding. Linton tubes are preferred for bleeding from fundal gastric varices. Balloon tamponade should be reserved as a temporizing measure until a more definitive treatment, such as TIPS, can be performed.

In patients with acute variceal bleeding refractory to pharmacologic or endoscopic therapy, a decrease in portal pressure through use of the TIPS procedure is effective in controlling bleeding and preventing rebleeding.[59] The TIPS procedure involves the placement of one or more stents between the hepatic vein and the portal vein (Fig. 44–6). TIPS (preferably with polytetrafluoroethylene-covered stents) is recommended for patients who fail to achieve hemostasis after a second attempt at endoscopic therapy.[12] TIPS provides an effective decompressive shunt without laparotomy and can be employed regardless of Child-Pugh score, unlike shunt surgery, which is restricted to Child-Pugh class A patients.[28] TIPS decreased the incidence of variceal rebleeding and decreased the incidence of deaths due to rebleeding.[60] There was a significantly increased rate of posttreatment encephalopathy found in TIPS-treated patients.

Treatment Recommendations: Variceal Hemorrhage

Patients require cautious resuscitation with colloids and blood products to correct intravascular losses and to reverse existing coagulopathies.[12,28,37] 4 Drug therapy with octreotide should be initiated early to control bleeding and facilitate diagnostic and therapeutic endoscopy. Therapy is initiated with an intravenous bolus of 50 mcg and is followed by a continuous infusion of 50 mcg

per hour for 3 to 5 days.[28,37] Monitor patients for hypo- or hyperglycemia, especially patients with diabetes, and assess for cardiac conduction abnormalities. Vasopressin is no longer recommended for control of variceal bleeding.[12,28,37] Endoscopy is recommended in any patient with suspected upper gastrointestinal bleeding due to ruptured varices. EVL is the recommended form of endoscopic therapy, but endoscopic sclerotherapy may be employed if EVL is technically difficult. An additional endoscopic therapy option is injection of the tissue adhesive N-butyl-cyanoacrylate for gastric varices. Short-term antibiotic prophylaxis (maximum 7 days) is recommended. Appropriate choices include norfloxacin 400 mg twice daily or intravenous ciprofloxacin if the oral route is unavailable. In patients with advanced cirrhosis in areas of high quinolone resistance, intravenous ceftriaxone 1 g daily may be preferred. Surgical shunts and TIPS are employed as salvage therapy in patients who have failed repeated endoscopy and vasoactive drug therapy.

Secondary Prophylaxis: Prevention of Rebleeding Because rebleeding after initial control of variceal hemorrhage occurs in a median of 60% of patients within 1 to 2 years without treatment and because rebleeding carries a mortality rate of 33%, it is inappropriate to simply observe patients for evidence of further bleeding.[24,61] Only patients who underwent shunt surgery or TIPS to control their initial acute bleeding require no further intervention as secondary prophylaxis.[28,37] Patients who underwent one of these procedures to treat their initial bleed should be referred for transplantation if they are a candidate.[28] Candidates include those with a Child-Pugh score greater than or equal to 7 or MELD score greater than or equal to 15. Combination therapy with β-adrenergic blockers and chronic EVL to eradicate varices is the best treatment option for secondary prophylaxis of variceal bleeding.[12,28,37] Secondary prophylaxis should be started as soon as possible following the acute bleed once the patient has had no bleeding for at least 24 hours and before the patient is discharged from the hospital. Alternatives for the secondary prevention of rebleeding include surgical or interventional shunting, but pharmacologic plus endoscopic interventions should be used as first-line therapy to prevent rebleeding.

Drug Therapy The combination of EVL and a nonselective β-adrenergic blocking agent provides the most rational approach for secondary prophylaxis because nonselective β-adrenergic blocking agents can protect against variceal rebleeding before variceal obliteration can be accomplished through EVL, and β-adrenergic blocking agents will also delay variceal recurrence.[28,37] EVL plus nonselective β-adrenergic blocker has been compared with EVL alone for the prevention of rebleeding.[62,63] Rebleeding rates were significantly lower in patients treated with combination therapy (23% and 14%) versus EVL alone (47% and 38%). A meta-analysis comparing combination endoscopic therapy (with either sclerotherapy or EVL) and nonselective β-adrenergic blocker versus either therapy alone found that combination therapy reduces overall and variceal rebleeding better than either therapy alone.[64] The combination of EVL and nonselective β-adrenergic blocker should be employed in any patient who experiences first or recurrent variceal bleeding while on either EVL or nonselective β-adrenergic blocker alone.[28,37]

The lowest rate of variceal rebleeding occurs in patients when pharmacologic therapy leads to a reduction in HVPG of greater than 20% of baseline or to a measurement less than 12 mm Hg.[61,65] Ideally, portal pressure monitoring would help to assess the response to nonselective β-adrenergic blocker therapy and identify responders from nonresponders earlier in the treatment course. In order to utilize the HVPG measurement for clinical decision making, the technique used to make this measurement would first have to be standardized, including the best time to perform the repeat HVPG measurement.[28,37]

CLINICAL CONTROVERSY

The combination of nonselective β-adrenergic blocker and isosorbide mononitrate could be more effective than nonselective β-adrenergic blocker therapy alone for lowering HVPG. Only one trial has evaluated nonselective β-adrenergic blocker plus isosorbide mononitrate verus nonselective β-adrenergic blocker alone.[66] Rebleeding rates were lower with combination therapy, but no statistically significant difference in rebleeding rates were attained. A randomized, controlled trial comparing variceal rebleeding in patients treated with combination therapy plus EVL versus patients treated with combination therapy alone found rebleeding rates that were significantly lower with combination therapy plus EVL versus combination therapy alone.[67] However, patients treated with combination therapy plus EVL had similar rebleeding rates compared with those treated with nonselective β-adrenergic blocker plus EVL. Patients treated with combination therapy are more likely to discontinue therapy than patients treated with nonselective β-adrenergic blocker therapy alone.[66] Whether nitrate therapy should be added to nonselective β-adrenergic blocker therapy in patients with prior history of variceal bleeding remains controversial, especially in patients who are able to undergo EVL. The unresolved questions surrounding HVPG measurement further compound this quandary.

Treatment Recommendations: Secondary Prophylaxis The combination of EVL plus pharmacologic therapy to prevent rebleeding is currently considered the most rational therapeutic approach.[28,37] Pharmacologic therapy should be initiated with a nonselective β-blocker such as propranolol 20 mg twice daily or nadolol at a dose of 20 mg once daily.[37] 3 β-Blocker therapy can be titrated to achieve a goal heart rate of 55 to 60 beats per minute or the maximal tolerated dose. Monitor patients for evidence of heart failure, bronchospasm, and glucose intolerance, particularly hypoglycemia in patients with insulin-dependent diabetes. EVL should be conducted every 1 to 2 weeks until variceal obliteration, and then the patient should be followed by surveillance endoscopy in 1 to 3 months and then every 6 to 12 months. Combination therapy with nonselective β-blocker plus isosorbide mononitrate can be considered in patients who are unable to undergo EVL. Patients who cannot tolerate or who fail pharmacologic and endoscopic interventions can be considered for TIPS or surgical shunting to prevent bleeding. A summary of evidence-based treatment recommendations regarding portal hypertension and variceal bleeding is found in Table 44–3.

Ascites and Spontaneous Bacterial Peritonitis

Patients with cirrhosis experience overt fluid retention and ascites as liver disease progresses.[10] The classic physical exam findings of ascites are a bulging abdomen with shifting flank dullness.[6] The development of ascites in patients with cirrhosis is an indication of advanced liver disease and is a poor prognostic sign.[6,10] The principle therapeutic goals for patients with ascites are to control the ascites; to prevent or relieve ascites-related symptoms such as dyspnea, abdominal pain, and abdominal distention; and to prevent life-threatening complications such as SBP and the hepatorenal syndrome.[10] Treatment of ascites is expected to have little effect on survival, however.[37] Workup includes a history and physical exam, abdominal paracentesis and/or ultrasound,

TABLE 44-3 Evidence-Based Table of Selected Treatment Recommendations: Variceal Bleeding in Portal Hypertension

Recommendation	Grade
Prevention of variceal bleeding	
Nonselective β-blocker therapy should be initiated in:	
Patients with small varices and criteria for increased risk of hemorrhage	IIaC
Patients with medium/large varices without high risk of hemorrhage	IA
Endoscopic variceal ligation (EVL) should be offered to patients who have contraindications or intolerance to nonselective β-blockers	IA
EVL may be recommended for prevention in patients with medium/large varices at high risk of hemorrhage instead of nonselective β-blocker therapy	IA
Treatment of variceal bleeding	
Short-term antibiotic prophylaxis should be instituted upon admission	IA
Vasoactive drugs should be started as soon as possible, prior to endoscopy, and maintained for 3–5 days	IA
Endoscopy should be performed within 12 hours to diagnose variceal bleeding and to treat bleeding with either sclerotherapy or EVL	IA
Secondary prophylaxis of variceal bleeding	
Nonselective β-blocker therapy plus EVL is the best therapeutic option for prevention of recurrent variceal bleeding	IA

Recommendation grading:
Class I–Conditions for which there is evidence and/or general agreement
Class II–Conditions for which there is conflicting evidence and/or a divergence of opinion
Class IIa–Weight of evidence/opinion is in favor of efficacy
Class IIb–Efficacy less well established
Class III–Conditions for which there is evidence and/or general agreement that treatment is not effective and/or potentially harmful
Level A–Data from multiple randomized trials or meta-analyses
Level B–Data derived from single randomized trial or nonrandomized studies
Level C–Only consensus opinion, case studies, or standard of care
Data from reference 28.

and ascitic fluid analysis.[6] The treatment of ascites is based on oral diuretics and is carried out in a slow, stepwise fashion.[37] Treatment of ascites should be initiated only in stable patients (e.g.; those without ongoing variceal hemorrhage, bacterial infection, or renal dysfunction).

SBP is an infection of ascitic fluid that occurs in the absence of any evidence of an intra-abdominal, surgically treatable source of infection.[6] SBP is a common complication that develops in 10% to 20% of patients hospitalized with severe liver disease, cirrhosis, and ascites.[37] The key mechanism behind the development of SBP is thought to be bacterial translocation.[68] Decreased motility of the gastrointestinal tract with disturbances of the gut flora, changes in the structure of the gastrointestinal tract, and reduced local and humoral immunity combine to lead to the free flow of microorganisms and endotoxins to the mesenteric lymph nodes. Most episodes of SBP are caused by *Escherichia coli*, *Klebsiella pneumonia*, and pneumococci.[6] Symptoms and signs of SBP include fever, abdominal pain, abdominal tenderness, rebound, encephalopathy, renal failure, acidosis, peripheral leukocytosis, and altered mental status.[6,68] Paralytic ileus, hypotension, and hypothermia are poor prognostic indicators.[68] Thirteen percent of patients with SBP present with no symptoms. For this reason, a diagnostic paracentesis with analysis of ascitic fluid should be performed in all patients admitted with ascites.[6] Spontaneous bacterial peritonitis is diagnosed when there is possible ascitic fluid bacterial culture and ascitic fluid cell counts show an absolute polymorphonuclear (PMN) leukocyte count of greater than or equal to 250 cells/mm^3.

Management of Ascites and Spontaneous Bacterial Peritonitis

The following treatment guidelines for the management of adult patients with ascites and spontaneous bacterial peritonitis were updated and approved by the Practice Guidelines Committee of the American Association for the Study of Liver Diseases (AASLD).

Ascites In adult patients with new-onset ascites as determined by physical exam or radiographic studies, abdominal paracentesis should be performed, and ascitic fluid analysis should include a cell count with differential, ascitic fluid total protein, and a serum-ascites albumin gradient (SAAG). If infection is suspected, ascitic fluid cultures should be obtained at the time of the paracentesis. The SAAG can accurately determine whether ascites is a result of portal hypertension or another process.[69] If the SAAG is greater than 1.1 g/dL, the patient almost certainly has portal hypertension and will usually be responsive to salt restriction and diuretics. If the SAAG is less than 1.1 g/dL, the patient likely does not have portal hypertension and, except in cases of nephrotic syndrome, is less likely to respond to salt restriction and diuretics. The treatment of ascites secondary to portal hypertension is relatively straightforward and includes abstinence from alcohol, sodium restriction, and diuretics.[6]

1 Abstinence from alcohol is an essential element of the overall treatment strategy. Abstinence from alcohol can result in improvement of the reversible component of alcoholic liver disease, resolution of ascites, or improved responsiveness of ascites to medical therapy. Patients with cirrhosis not caused by alcohol have less reversible liver disease, and, by the time ascites is present, these patients may be best managed with liver transplantation rather than protracted medical therapy.

Beyond avoidance of alcohol, the primary treatment of ascites due to portal hypertension and cirrhosis is salt restriction and oral diuretic therapy. Fluid loss and weight change depend directly on sodium balance in these patients. Evaluation of urinary sodium excretion, preferably utilizing a 24-hour urine collection, may be helpful when rapidity of weight loss is less than desired.[69,70] Severe hyponatremia, defined as serum sodium less than a threshold of 120 to 125 mEq/L, does warrant fluid restriction.[6] However, rapid correction of asymptomatic hyponatremia is not recommended as patients with cirrhosis are usually asymptomatic until their serum sodium concentrations are less than 110 mEq/L or unless the decline in serum sodium is rapid.

Diuretic Therapy 5 The AASLD practice guidelines recommend that diuretic therapy be initiated with the combination of spironolactone and furosemide. At one time, spironolactone was commonly recommended for initial therapy as a single agent. However, due to the likelihood for development of drug-induced hyperkalemia with spironolactone when used as monotherapy, the drug is now recommended only for use as a lone diuretic agent in patients with minimal fluid overload. If tense ascites is present, paracentesis should be performed prior to institution of diuretic therapy and salt restriction. For patients who respond to diuretic therapy, this approach is preferred over the use of serial paracenteses. In patients with refractory ascites, serial paracenteses may be employed. Albumin infusion postparacentesis is controversial, but reasonable for extraction volumes exceeding 5 liters. Laboratory tests for renal function and electrolytes need to be monitored during therapy. Referral for liver transplantation should be made in patients with refractory ascites. TIPS is a therapeutic modality for the treatment of refractory ascites that may be considered in appropriately selected patients. Peritoneovenous shunting may be considered in treatment refractory patients who are not candidates for paracenteses, transplant, or TIPS.

Spontaneous Bacterial Peritonitis

Relatively broad-spectrum antibiotic therapy that adequately covers the three most commonly encountered pathogens (*Escherichia coli*, *Klebsiella pneumoniae*, and pneumococci) is warranted in patients with documented or suspected SBP.[6,37,68] Empirical therapy should not be delayed while awaiting culture results. In some patients, signs and symptoms of infection are present such as fever, abdominal pain, and unexplained encephalopathy at the bacterascites stage (i.e., signs and symptoms are present before the PMN count in the ascitic fluid is elevated).[6] In these patients, signs and symptoms of infection justify empiric antibiotic therapy until culture results are known, regardless of the PMN count in the ascitic fluid.

Cefotaxime 2 g every 8 hours, or a similar third-generation cephalosporin, is considered the drug of choice for SBP.[6] Cefotaxime is more effective than the combination of ampicillin and tobramycin.[71] A 5-day course of antibiotic therapy was as efficacious as 10 days of therapy in a randomized trial involving 100 patients with SBP.[72] Ofloxacin 400 mg every 12 hours administered orally for an average of 8 days is equivalent to intravenous cefotaxime for treatment of SBP in patients without vomiting, shock, significant hepatic encephalopathy, or serum creatinine over 3 mg/dL.[73] Intravenous ciprofloxacin offers another potential treatment alternative.[74] Patients with SBP who previously received quinolone therapy as prophylaxis should be treated with an alternative agent since patients who have received quinolone therapy may become infected with quinolone-resistant flora.[6]

Secondary bacterial peritonitis, ascitic fluid infection caused by a surgically treatable intraabdominal source, can masquerade as SBP. Free perforation should be considered when multiple or atypical organisms are cultured, a very high ascitic fluid PMN count is seen, or when at least two of the following are seen on ascitic fluid analysis: total protein greater than 1 g/dL, lactate dehydrogenase greater than the upper limit of normal for serum, and glucose less than 50 mg/dL.[75] A 48-hour follow-up PMN count that rises above pretreatment levels despite antibiotic treatment is indicative of secondary nonperforation peritonitis.[76] Patients with free perforation or nonperforation secondary peritonitis should receive a third-generation cephalosporin plus anaerobic coverage in addition to undergoing laparotomy.[75]

Treatment Recommendations: Ascites and Spontaneous Bacterial Peritonitis

Adult patients admitted to the hospital with new-onset ascites should have an abdominal paracentesis performed to establish the SAAG, the ascitic fluid cell count and differential, and the ascitic fluid total protein. If ascitic fluid infection is suspected, ascitic fluid should be cultured at the bedside. 1 Patients who drink alcohol should be strongly discouraged from further alcohol use. 5 Sodium restriction to 2,000 mg/day, together with spironolactone and furosemide, is the main stay of therapy. Diuretic therapy should be initiated with single morning doses of spironolactone 100 mg and furosemide 40 mg administered orally. Titrate diuretic therapy every 3 to 5 days using the 100 mg:40 mg ratio to attain adequate natriuresis and weight loss (reasonable daily weight loss goal is 0.5 kg).[77] Maximum daily doses are 400 mg spironolactone and 160 mg furosemide.[69,70] This combination ratio is used because it usually maintains normokalemia.[6] Fluid restriction, unless the serum sodium is less than 120 to 125 mEq/L, and bed rest are not recommended. Monitor urinary sodium excretion using a 24-hour urine collection and monitor serum potassium and renal function frequently. Avoid rapid correction of asymptomatic hyponatremia in patients with cirrhosis. If tense ascites is present, paracentesis should be performed prior to institution of diuretic therapy and salt restriction. For patients who respond to diuretic therapy, this approach is preferred over the use of serial paracenteses. Discontinue diuretic therapy in patients who experience uncontrolled or recurrent encephalopathy, severe hyponatremia (serum sodium less than 120 mEq/L) despite fluid restriction, or renal insufficiency (serum creatinine greater than 2 mg/dL). Serial paracenteses may be considered for patients with refractory ascites and albumin infusion of 6 to 8g/L of fluid removed can be considered postparacentesis when paracentesis volumes exceed 5 L.

Patients with ascitic fluid PMN counts greater than or equal to 250 cells/mm^3 should receive empiric antibiotic therapy with intravenous cefotaxime 2 g every 8 hours or a similar third-generation cephalosporin. Oral ofloxacin 400 mg twice daily may be an alternative option in patients without prior exposure to quinolones, vomiting, shock, severe encephalopathy, or serum creatinine over 3 mg/dL. Patients with ascitic fluid PMN counts less than 250 cells/mm^3 but with signs and symptoms of infection (symptoms such as abdominal pain, abdominal tenderness, and fever) should also receive empiric antibiotic treatment. Patients with ascitic fluid PMN counts greater than or equal to 250 cells/mm^3 and suspicion of SBP should also receive 1.5 g of albumin per kilogram body weight within 6 hours of detection and 1 g per kilogram body weight on day 3 if they also have a serum creatinine over 1 mg/dL, blood urea nitrogen over 30 mg/dL, or total bilirubin over 4 mg/dL.

6 All patients who have survived an episode of SBP should receive long-term antibiotic prophylaxis with daily norfloxacin 400 mg or double strength trimethoprim-sulfamethoxazole. Long-term prophylaxis should also be considered for the prevention of SBP in patients with low-protein ascites (less than 1.5 g/dL) who also have one of the following: serum creatinine greater than or equal to 1.2 mg/dL, blood urea nitrogen greater than or equal to 25 mg/dL, serum sodium less than or equal to 130 mEq/L, or Child-Pugh score of greater than or equal to 9 with bilirubin greater than or equal to 3 mg/dL. Short-term prophylaxis (7 days) is indicated in patients with cirrhosis and gastrointestinal hemorrhage. A summary of evidence-based treatment recommendations regarding ascites and SBP is found in Table 44–4.

HEPATIC ENCEPHALOPATHY

The clinical manifestations of HE vary widely.[78] Patients with minimal HE do not suffer from clinically overt cognitive dysfunction; nevertheless, it adversely affects their ability to function socially and perform in the workplace, and it may also affect their ability to drive safely.[13] Episodic HE refers to precipitated, spontaneous, or recurrent acute episodes of HE. *Recurrent HE* refers to two spontaneous or precipitated episodes of HE that occur within 1 year. Persistent HE refers to mild, severe, or treatment-dependent symptoms that are chronic in nature and negatively impact a patient's quality of life.

The prevalence of HE among cirrhotics is variable but may be found in up to 70% of patients. To determine the severity of HE, a grading system that relates neurologic and neuromuscular signs can be used (Table 44–5). Presently, the primary substances thought to be involved in the development of HE are ammonia, glutamate, manganese, and the γ-aminobutyric acid (GABA)-benzodiazepine receptor agonists.[13,78]

Management of Hepatic Encephalopathy

Episodic HE may develop in a clinically stable cirrhotic patient as the result of a precipitating event.[13] Table 44–6 lists the most commonly encountered precipitating factors and suggests general treatment alternatives. Table 44–7 describes the treatment goals for patients with HE and contrasts the differences between episodic

TABLE 44-4 Evidence-Based Table of Selected Treatment Recommendations: Ascites and Spontaneous Bacterial Peritonitis

Recommendation	Grade
Ascites	
Paracentesis should be performed in patients with apparent new-onset ascites	IC
Sodium restriction of 2,000 mg/day should be instituted as well as oral diuretic therapy with spironolactone and furosemide	IIaA
Diuretic-sensitive patients should be treated with sodium restriction and diuretics rather than serial paracentesis	IIaC
Refractory ascites	
Serial therapeutic paracenteses may be performed	IC
Postparacentesis albumin infusion of 6 to 8 g/L of fluid removed can be considered if more than 5 L are removed during paracentesis	IIaC
Treatment of SBP	
If ascitic fluid PMN counts are greater than 250 cells/mm^3, empiric antibiotic therapy should be instituted (cefotaxime 2 g every 8 hours)	IA
If ascitic fluid PMN counts are less than 250 cells/mm^3, but signs or symptoms of infection exist, empiric antibiotic therapy should be initiated while awaiting culture results	IB
Ofloxacin 400 mg twice daily may be substituted for cefotaxime in patients without vomiting, shock, grade II or higher encephalopathy, or serum creatinine greater than 3 mg/dL and if there is no prior exposure to quinolones	IIaB
If ascitic fluid polymorphonuclear leukocyte counts are greater than 250 cells/mm^3, clinical suspicion of SBP is present, and the patient has a serum creatinine greater than 1 mg/dL, blood urea nitrogen greater than 30 mg/dL, or total bilirubin over 4 mg/dL, 1.5 g/kg albumin should be infused within 6 hours of detection and 1 g/kg albumin infusion should also be given on day 3	IIaB
Prophylaxis against SBP	
Short-term antibiotic prophylaxis should be used for 7 days to prevent SBP in cirrhosis patients with gastrointestinal hemorrhage	IA
Patients who survive an episode of SBP should receive long-term prophylaxis with either daily norfloxacin or trimethoprim-sulfamethoxazole	IA
Patients with low protein ascites (less than 1.5 g/dL) plus at least one of the following: serum creatinine greater than or equal to 1.2 mg/dL, blood urea nitrogen greater than or equal to 25 mg/dL, serum sodium less than or equal to 130 mEq/L, or Child-Pugh score of greater than or equal to 9 with bilirubin greater than or equal to 3 mg/dL may also justifiably receive long-term norfloxacin or sulfamethoxazole/trimethoprim as prophylaxis	IB

Recommendation grading:
Class I–Conditions for which there is evidence and/or general agreement
Class II–Conditions for which there is conflicting evidence and/or a divergence of opinion
Class IIa–Weight of evidence/opinion is in favor of efficacy
Class IIb–Efficacy less well established
Class III–Conditions for which there is evidence and/or general agreement that treatment is not effective and/or potentially harmful
Level A–Data from multiple randomized trials or meta-analyses
Level B–Data derived from single randomized trial or nonrandomized studies
Level C–Only consensus opinion, case studies, or standard of care
Data from reference 6.

and persistent HE. The general approach to the management of HE is to first identify and treat any precipitating factors, and, when associated with a precipitant, the clinical features of HE may resolve after the precipitating factor is treated or removed.[13,14] The development of overt HE in cirrhosis is associated with increased mortality.[79]

Treatment approaches for episodic and persistent HE include (a) reducing ammonia blood concentrations by dietary restrictions and drug therapy aimed at inhibiting ammonia production or enhancing its removal and (b) inhibition of the γ-aminobutyric acid (GABA)-benzodiazepine receptors. Additionally, treatment for persistent HE should include avoidance and prevention of precipitating factors in an effort to avoid acute decompensation.[14]

Hyperammonemia

7 Treatment interventions to reduce ammonia blood concentrations are recommended in patients with HE.[14] Decreasing ammonia blood concentrations by reducing the nitrogenous load from the gut remains a mainstay of therapy for patients with HE. Treatment options most commonly used to decrease ammonia load from the gut include nutritional management, nonabsorbable disaccharides, and antibiotics.

Guidelines for nutritional support of patients with liver disease have been published by the European Society for Parenteral and Enteral Nutrition.[80] Protein withdrawal is a cornerstone of treatment for patients during acute episodes of HE.[14] However, prolonged restriction can lead to malnutrition and poorer prognosis among HE patients. Therefore, once successful reversal of HE symptoms is achieved, protein is added back to the diet in combination with other therapies until a target of 1 to 1.5 g/kg per day is reached. Vegetable-source and dairy-source protein may be preferable to meat-source protein because the latter contains a higher calorie to nitrogen ratio. Also, the higher fiber content of vegetable protein lowers colonic pH, increasing catharsis. Most patients will tolerate at least 1 g/kg/day of standard proteins without becoming encephalopathic.[81] Branched-chain amino acid (BCAA) formulations may provide a better-tolerated source of protein in those patients with protein intolerance.[14] Bowel cleansing using cathartics or lactulose enemas (see following discussion) results in rapid removal of ammonia substrate from the colon and may be combined with dietary intervention to help the patient eliminate ammonia and tolerate dietary protein.

The use of lactulose, a nonabsorbable disaccharide, is standard therapy for both acute and chronic HE. Lactulose, when administered orally through ingestion or a nasogastric tube, passes through the gastrointestinal tract and reaches the colon unchanged. It can also be administered by retention enema. Lactulose is metabolized by gut flora into acetic acid and lactic acid, which lower colonic pH and create a cathartic effect.

Lactulose administration lowers ammonia levels in the blood in several ways: (a) through creation of a laxative effect that reduces

TABLE 44-5 Grading System for Hepatic Encephalopathy

Grade	Level of Consciousness	Personality/Intellect	Neurologic Abnormalities
0	Normal	Normal	None
1	Inverted sleep patterns/restless	Mild confusion, euphoria or depression, decreased attention, irritable, slowing of ability to perform mental tasks	Slight tremor, apraxia, incoordination
2	Lethargic, drowsy, intermittent disorientation (usually for time)	Obvious personality changes, inappropriate behavior, gross deficits in ability to perform mental tasks	Asterixis, abnormal reflexes
3	Somnolent but arousable, markedly confused, disorientation to time and/or place, amnesia	Unable to perform mental tasks, occasional fits of rage, speech present but incomprehensible	Abnormal reflexes
4	Coma/unarousable	None	Decerebrate, Babinski sign present

Data from reference 13.

TABLE 44-6 Portosystemic Encephalopathy: Precipitating Factors and Therapy

Factor	Therapy Alternatives
Gastrointestinal bleeding	
Variceal	Band ligation/sclerotherapy Octreotide
Nonvariceal	Endoscopic therapy Proton pump inhibitors
Infection/sepsis	Antibiotics Paracentesis
Electrolyte abnormalities	Discontinue diuretics Fluid and electrolyte replacement
Sedative ingestion	Discontinue sedatives/tranquilizers Consider reversal (flumazenil/naloxone)
Dietary excesses	Limit daily protein Lactulose
Constipation	Cathartics Bowel cleansing/enema
Renal insufficiency	Discontinue diuretics Discontinue NSAIDs, nephrotoxic antibiotics Fluid resuscitation

Data from reference 13, 14, and 78.

the time period available for ammonia absorption, (b) through leaching of ammonia from the circulation into the colon and increasing bacterial uptake of ammonia by colonic bacteria, and (c) through reducing ammonia production by the small intestine by interfering directly with the uptake of glutamine by the intestinal wall and its subsequent metabolism to ammonia.[82] Upon evaluation of the numerous clinical trials studying the effectiveness of lactulose in the treatment of HE, one may determine that the standards of evidence-based medicine have not been met.[14,83,84] In fact, lactulose plus neomycin was not better than placebo for the management of acute HE.[85] Despite this and because reevaluation of lactulose for the management of HE (especially acute HE) would require a new clinical trial, bowel cleansing through lactulose administration remains a cornerstone in HE therapy.[14] Inhibiting the activity of urease-producing bacteria by using neomycin or metronidazole can decrease production of ammonia.[86,87] Neomycin at doses of 3 to 6 g daily can be given for 1 to 2 weeks during an acute episode of HE.[14] For persistent HE, a dose of 1 to 2 g daily could be used with periodic renal and annual auditory monitoring. Despite poor absorption, chronic use of neomycin can lead to irreversible ototoxicity, nephrotoxicity, and the possibility of staphylococcal superinfection. As such, neomycin should not be considered first-line therapy for HE. In patients with an inadequate response to lactulose alone, combination therapy with neomycin may be tried. Metronidazole initiated at 250 mg twice daily may also produce a favorable clinical response in HE. However, neurotoxicity caused by impaired hepatic clearance of the drug may be problematic.

TABLE 44-7 Treatment Goals: Episodic and Persistent Hepatic Encephalopathy

Episodic HE	Persistent HE
Control precipitating factor	Reverse encephalopathy
Reverse encephalopathy	Avoid recurrence
Hospital/inpatient therapy	Home/outpatient therapy
Maintain fluid and hemodynamic support	Manage persistent neuropsychiatric abnormalities
	Manage chronic liver disease
Expect normal mentation after recovery	High prevalence of abnormal mentation after recovery

Ammonia generated by *Helicobacter pylori* in the stomach may be associated with precipitating or worsening HE in patients with cirrhosis.[88] However, a prospective clinical trial showed no significant improvement in mental status or serum ammonia levels in patients with HE who underwent *H. pylori* eradication.[89] Therefore, routine eradication of *H. pylori* is not recommended.[14]

Rifaximin is a synthetic antibiotic structurally similar to rifamycin with a systemic absorption of only 0.4%.[82] Rifaximin lowers blood ammonia levels and improves neuropsychiatric symptoms in HE. Rifaximin 1,200 mg/day has been compared with lactitol 60 g/day in patients with grade I to III HE for 5 to 10 days.[90] Comparable percentages of patients showed clinical improvement at the end of the treatment period; however, improvements in blood ammonia concentrations and in the HE index were significantly greater among rifaximin-treated patients. There was also a higher number of patients who showed complete resolution of their neuropsychiatric symptoms with rifaximin treatment versus the nonabsorbable disaccharide lactitol. Rifaximin has also been compared with neomycin in patients with grade I to III HE.[91] In this randomized, double-blind comparison, patients were treated for 21 days with either rifaximin 1,200 mg daily or neomycin 3 g/day. While significant improvements were seen in both groups, improvements in psychometric performance and blood ammonia concentrations were significantly greater in patients treated with rifaximin. Also, while no adverse events were reported in the rifaximin-treatment group, nearly a fourth of neomycin-treated patients experienced increases in blood urea nitrogen and serum creatinine levels, and nearly a third reported nausea, abdominal pain, and vomiting.

CLINICAL CONTROVERSY

Rifaximin has been shown to be effective in the treatment of HE and has a favorable side effect profile as compared with other antibiotics in use for HE today.[91] It has been found to be more effective in some HE-related measurement parameters as compared with lactitol.[90] Though studies to date have enrolled relatively small numbers of patients and even though it does not carry the indication for HE in the United States, rifaximin is largely considered second-line therapy for patients with HE who fail therapy or have inadequate results with lactulose. Whether or not rifaximin should be considered as first-line therapy over lactulose or whether rifaximin should be considered first-line therapy in addition to lactulose remains controversial. Rifaximin costs approximately 12 times more than lactulose.[82] However, if rifaximin is more effective than lactulose and prevents other costs, such as hospitalizations, treatment with rifaximin or rifaximin plus lactulose may actually be more cost effective than therapy with lactulose alone. A large multicenter trial comparing rifaximin plus lactulose with placebo plus lactulose in patients with recurrent episodic HE is under way and should provide some further information about rifaximin and its place in the therapy of HE in the future.

Ammonia removal can be enhanced by stimulating its detoxification. This is done by supporting alternative metabolic pathways, which can reduce blood ammonia concentrations. L-Ornithine L-aspartate stimulates residual hepatic urea cycle activity and promotes peripheral glutamine synthesis.[92] Intravenous L-Ornithine L-aspartate is effective in cirrhotic patients with grade 1 and grade 2 HE to reduce blood ammonia and improve clinical symptoms of

HE with clinical response rates similar to those of lactulose.[93] Oral L-Ornithine L-aspartate is effective at reducing blood ammonia and improving clinical symptoms in patients with grade 2 HE.[94]

Zinc is a cofactor of urea cycle enzymes and can be deficient in cirrhotic patients, especially in cases of malnourishment.[14] Zinc replacement has mixed results for decreasing ammonia levels and improving symptoms of HE.[95,96] In a controlled trial in cirrhotic patients with mild HE, the administration of zinc sulfate 600 mg/day for 3 months resulted in increased urea formation and lower ammonia levels along with improvement in psychological test scores.[96] Other therapies studied in HE to lower the ammonia load from the gut include sodium benzoate and probiotics like *Lactobacillus acidophilus* and *Enterococcus faecium* SF 68.[14]

Drugs Affecting Neurotransmission

The GABA-receptor complex is the primary inhibitory neural network within the central nervous system. An enhanced GABAergic tone and an increased amount of endogenous benzodiazepines may contribute to HE.[97] Based on evidence of an increase in benzodiazepine receptor ligands in patients with hepatic encephalopathy, flumazenil has been evaluated for the treatment of HE.[98] Among five prospective, placebo-controlled trials, three reported benefit with flumazenil, whereas two found no difference when compared to placebo. With dosages of 0.2 to 15 mg IV, response rates were variable, ranging from 17% to 78%. Improvements, however, were often transient. Flumazenil 1 mg intravenous bolus may be considered for short-term therapy in refractory patients with suspected benzodiazepine intake, but cannot be recommended for routine clinical use.[14]

Alterations of dopaminergic neurotransmission have also been thought to play a role in the symptoms of HE, particularly the extrapyramidal signs.[14] Improvements of extrapyramidal symptoms have been reported with bromocriptine therapy.[99] Bromocriptine 30 mg twice daily is indicated for chronic HE treatment in patients who are unresponsive to other therapies.[14] Prolactin levels may become elevated during bromocriptine treatment, and ototoxicity is possible.[14,82] Bromocriptine should be avoided in patients with ascites.[82]

Treatment Recommendations: Hepatic Encephalopathy

Treatment recommendations depend on the type of HE being managed: episodic HE, persistent HE, or minimal HE.[37] The general approach to the management of HE is first to identify patients with acute episodic HE and then to provide aggressive management of any precipitating events (see Table 44–7).[14] When the precipitating event has been discovered and appropriate therapy initiated, then steps to rapidly reverse the encephalopathy should be implemented.

7 The mainstay of therapy of HE involves measures to lower blood ammonia concentrations and includes diet therapy, lactulose, and antibiotics alone or in combination with lactulose. Other commonly used adjunctive therapies include zinc replacement in patients with zinc deficiency, flumazenil, and possibly bromocriptine.

In patients with episodic HE, protein is withheld or limited while maintaining the total caloric intake until the clinical situation improves. Then dietary protein is titrated back up based on tolerance, increasing gradually to a total of 1 to 1.5 g/kg per day. Consider the substitution of meat-source protein with vegetable or dairy protein. Zinc sulfate supplementation at a dose of 220 mg twice daily is recommended for long-term management in patients with cirrhosis who are zinc deficient.

In episodic HE, lactulose is initiated at a dose of 45 mL orally every hour (or by retention enema: 300 mL lactulose syrup in 1 L water held for 60 minutes) until catharsis begins. The dose is then decreased to 15 to 45 mL orally every 8 to 12 hours and titrated to produce two to three soft stools per day. The enema is retained for 1 hour with the patient in the Trendelenburg position. For chronic encephalopathy, dosing is the same except that the initial hourly administration is not required. Patients are maintained on this regimen to prevent recurrence of episodic HE. Monitor electrolytes periodically, follow patients for changes in mental status, and titrate to the number of stools as already described.

Antibiotic therapy with either metronidazole (initiated at 250 mg twice daily but titrated up to four times daily in the literature) or neomycin (dose at 3 to 6 g/day for 1 to 2 weeks for episodic HE and 1 to 2 g/day for persistent HE) are reserved for patients who have not responded to diet and lactulose therapy and when the combination may provide additive effects and improved clinical response. Because rifaximin 400 mg three times daily provides similar effectiveness and has less risk of side effects as compared with other antibiotic options, rifaximin is often used today as second-line therapy for patients who have inadequate response to lactulose or are unable to tolerate or adhere to therapy with lactuose.[37]

SYSTEMIC COMPLICATIONS

In addition to the more common complications of chronic liver disease discussed earlier, other complications can occur, including hepatorenal syndrome, hepatopulmonary syndrome, coagulation disorders, and endocrine dysfunction.

Hepatorenal syndrome, which is a functional renal failure in the setting of cirrhosis, occurs in the absence of structural kidney damage.[100] It develops in patients with cirrhosis as a result of intense renal vasoconstriction, which results from extreme systemic vasodilatation. The resultant reduction in blood supply to the kidneys causes avid sodium retention and oliguria. As liver disease progresses, systemic vasodilatation worsens and, subsequently, increased renal vasoconstriction occurs and renal blood flow is further decreased. As this occurs, the heart's response becomes insufficient to maintain perfusion pressure, which the kidneys rely heavily upon at this point to maintain adequate blood flow. Hepatorenal syndrome is common and develops in approximately 20% of hospitalized patients with cirrhosis.

Management of hepatorenal syndrome begins with a first step of discontinuing diuretics and any other medication that could potentially decrease effective blood volume and to expand the intravascular volume with intravenous albumin at a dose of 1 g/kg up to a maximum of 100 g.[37] Precipitating factors such as infection, fluid loss, and blood loss should be investigated and treated if found. Liver transplantation is the only definitive therapy for hepatorenal syndrome and the only therapy that will prolong survival. Therapies used to bridge patients until transplantation include arteriolar vasoconstrictor based treatments with terlipressin or midodrine plus octreotide used in addition to intravenous albumin infusion as already discussed.

Hepatopulmonary syndrome affects somewhere between 5% and 32% of patients with cirrhosis.[101] This abnormality is characterized by a defect in arterial oxygenation, which is caused by the pulmonary vascular dilatation that occurs in the presence of liver disease. Less commonly, pleural and pulmonary arteriovenous shunting can occur as well as portopulmonary venous anastomoses. These patients present with dyspnea on exertion, at rest, or both. Cirrhotic patients with these findings should be evaluated for hepatopulmonary syndrome, which is diagnosed based upon the presence of arterial hypoxemia. Arterial hypoxemia is defined based on measurements of the partial pressure of oxygen that are performed with patients sitting and at rest. Testing for an increased alveolar–arterial oxygen gradient is also particularly important as this gradient can rise abnormally before the patient's partial pressure of oxygen measurement becomes abnormally low. Long-term management requires supportive therapy with supplemental

oxygen. The prognosis for these patients is poor. Ultimately, liver transplantation offers the best chance for long-term recovery.

Coagulation disorders occur in patients with chronic liver disease because the liver plays a central role in the maintenance of hemostasis since it is the site for synthesis of a majority of the proteins involved in the regulation of coagulation and fibrinolysis.[15] These disorders increase the risk of bleeding and tend to become more profound as the liver failure becomes more severe. Correction of the coagulopathy is essential for patients actively bleeding. The pathophysiology of the coagulopathy is complex and involves impaired synthesis of clotting factors, excessive fibrinolysis, disseminated intravascular coagulation, thrombocytopenia, and platelet dysfunction. Acute therapy involves platelet transfusions for thrombocytopenia and fresh frozen plasma for prolongation of the PT because of clotting factor deficiencies.[37]

The presence of cirrhosis can produce abnormal circulating levels of various hormones.[102] Hypogonadism, diabetes mellitus, osteoporosis, and thyroid disorders are among the endocrine disorders that may develop related to advanced liver disease. Erectile dysfunction related to hypogonadism can be treated with the administration of testosterone and the removal of causative factors such as alcohol.

LIVER TRANSPLANTATION

The complications seen in patients with chronic liver disease are essentially functional as a secondary effect of the circulatory and metabolic changes that accompany liver failure. Consequently, liver transplantation is the only treatment that can offer a cure for complications of end-stage cirrhosis.

PHARMACOKINETIC AND PHARMACODYNAMIC CHANGES IN LIVER FAILURE

Cirrhosis modulates the behavior of drugs in the body by inducing kinetic alterations in drug absorption, distribution, and clearance.[103] Additionally, patients with cirrhosis may exhibit pharmacodynamic changes with increased sensitivity to the effects of certain drugs, namely opiates, benzodiazepines, and nonsteroidal antiinflammatory drugs (NSAIDs). These pharmacodynamic changes are separate and distinct from the enhancement of drug effects seen in cirrhosis patients as a result of pharmacokinetic changes. Hepatic drug clearance is primarily dependent upon protein binding, hepatic blood flow, and metabolic enzyme activity. The pathophysiologic changes that occur in patients with cirrhosis, including reduced liver blood flow, intra- and extrahepatic portal-systemic shunting, diminished metabolic and synthetic function, and capillarization of the sinusoids, can have a significant impact on each of these factors. The consequence of these changes is a reduction in intrinsic metabolic activity, a reduction in the delivery of blood to the liver that decreases clearance and prolongs half-life, and a reduction in the degree of protein binding that increases the fraction of unbound drug in the serum. Finally, patients with cirrhosis frequently accumulate large amounts of interstitial fluid resulting in substantial changes in the volume of distribution, which also prolongs drug half-life. These changes occur most commonly in combination in patients with cirrhosis and are dynamic throughout the disease course. The effect that these changes will have depends on the drug and the type of biotransformation that the drug undergoes.

Drugs with a high extraction ratio (high-extraction drugs) are dependent on blood flow for metabolism, and the rate of metabolism will be sensitive to changes in blood flow. Drugs with a low extraction ratio (low-extraction drugs) are dependent on intrinsic metabolic activity for metabolism, and the rate of metabolism will reflect changes in intrinsic clearance and protein binding. Furthermore, hepatic biotransformation involves two types of metabolic processes: phase I reactions and phase II reactions. Phase I reactions involve the cytochrome P450 system and include hydrolysis, oxidation, dealkylation, and reduction reactions. Phase II reactions involve conjugation of the drug with an endogenous molecule such as sulfate or an amino acid, rendering it more water soluble and enhancing its elimination. Drugs metabolized by phase I reactions, especially oxidation, tend to be significantly impaired in patients with cirrhosis, whereas drugs eliminated by conjugation are relatively unaffected.

The variability and complexity of the interaction between the extent and severity of liver disease and individual characteristics of the drug make it difficult to predict the degree of pharmacokinetic perturbation in an individual patient. Unfortunately, there are no sensitive and specific clinical or biochemical markers that allow us to quantify the extent of liver insufficiency or the degree of metabolic activity. In addition, renal insufficiency and alterations that commonly accompany cirrhosis further complicate empiric dosing recommendations in these patients. Dosing recommendations are most commonly nonspecific, with recommendations labeled for patients with mild to moderate liver impairment. Dosing information for patients with more severe liver impairment is not available. As a result, when patients with cirrhosis require therapy with drugs that undergo hepatic metabolism (e.g., benzodiazepines), monitoring response to therapy and anticipating drug accumulation and enhanced effects is essential. In the case of benzodiazepines, selection of an agent such as lorazepam, an intermediate-acting agent that is metabolized via conjugation and has no active metabolites, is easier to monitor than a drug such as diazepam, a long-acting benzodiazepine that is oxidized in the liver and has an active metabolite with a long half-life of its own.

PHARMACOECONOMIC CONSIDERATIONS

Two studies, both related to the prevention of variceal bleeding and published recently, are mentioned here.[104,105] A recent analysis provides evidence that HVPG monitoring is not cost-effective for use in patients with varices and no history of variceal bleeding as compared to treatment with standard β-blocker therapy without invasive monitoring.[104] A cost-utility evaluation of secondary prophylaxis therapies concluded that patients are best served by treatment with either endoscopic band ligation or endoscopic band ligation plus medical management as compared with TIPS placement.[105] Because treatment approaches for patients with cirrhosis can range from supportive medical therapy to repeated endoscopic procedures with serious complications to liver transplantation, the need for application of economic analysis is obvious. Of critical importance is the question of when, in the course of chronic liver disease, the various treatment interventions are employed and whether liver transplantation should be attempted earlier, thereby avoiding most of the complications associated with chronic liver disease.

EVALUATION OF THERAPEUTIC OUTCOMES

Table 44–8 summarizes the management approach for patients with cirrhosis, including monitoring parameters and therapeutic outcomes. Cirrhosis is generally a chronic progressive disease that requires aggressive medical management to prevent or delay common complications. Table 44–8 also lists monitoring criteria that need to be carefully followed in order to achieve the maximum benefit from the medical therapies employed and prevent adverse effects. A therapeutic plan including therapeutic end points for each medical and diet therapy needs to be developed and discussed with the patient.

TABLE 44-8 Management Approach and Outcome Assessments

Complication	Treatment Approach	Monitoring Parameter	Outcome Assessment
Ascites	Diet, diuretics, paracentesis, TIPS	Daily assessment of weight	Prevent or eliminate ascites and its secondary complications
Spontaneous bacterial peritonitis	Antibiotic therapy, prophylaxis if undergoing paracentesis	Evidence of clinical deterioration (e.g., abdominal pain, fever, anorexia, malaise, fatigue)	Prevent/treat infection to decrease mortality
Variceal bleeding	Pharmacologic prophylaxis	Child-Pugh score, endoscopy, CBC	Appropriate reduction in heart rate and portal pressure
	Endoscopy, vasoactive drug therapy (octreotide), ligation or sclerotherapy, volume resuscitation, pharmacologic prophylaxis	CBC, evidence of overt bleeding	Acute: control acute bleedChronic: variceal obliteration, reduce portal pressures
Coagulation disorders	Blood products (PPF, platelets), vitamin K	CBC, prothrombin time, platelet count	Normalize PT time, maintain/improve hemostasis
Hepatic encephalopathy	Ammonia reduction (lactulose, antibiotics), elimination of drugs causing CNS depression, limit excess protein in diet	Grade of encephalopathy, EEG, psychological testing, mental status changes, concurrent drug therapy	Maintain functional capacity, prevent hospitalization for encephalopathy, decrease ammonia levels, provide adequate nutrition
Hepatorenal syndrome	Eliminate concurrent nephrotoxins (NSAIDs), decrease or discontinue diuretics, volume resuscitation, liver transplantation	Serum and urine electrolytes, concurrent drug therapy	Prevent progressive renal injury by preventing dehydration and avoiding other nephrotoxins Liver transplantation for refractory hepatorenal syndrome
Hepatopulmonary syndrome	Paracentesis to relieve ascites, O_2 therapy	Dyspnea, presence of ascites	Acute: relief of dyspnea and hypoxiaChronic: manage ascites as above

CBC, complete blood cell count; CNS, central nervous system; EEG, electroencephalogram; PT, prothrombin time; NSAID, nonsteroidal antiinflammatory drug; PPF, plasma protein fraction; TIPS, transjugular intrahepatic portosystemic shunt.

ABBREVIATIONS

AAA: aromatic amino acid

AASLD: American Association for the Study of Liver Diseases

ALT: alanine transaminase

AST: aspartate transaminase

BCAA: branched-chain amino acid

EGD: esophagogastroduodenoscopy

EVL: endoscopic variceal ligation

GABA: γ-aminobutyric acid

GGT: γ-glutamyl transpeptidase

HE: hepatic encephalopathy

HVPG: hepatic venous pressure gradient

MELD: Model for End-stage Liver Disease

NSAIDs: non-steroidal anti-inflammatory drugs

PMN: polymorphonuclear

PT: prothrombin time

SAAG: serum-ascites albumin gradient

SBP: spontaneous bacterial peritonitis

TIPS: transjugular intrahepatic portosystemic shunt

UNOS: United Network for Organ Sharing
